THE REPORT OF THE AMERICAN PEDI- ATRIC SOCIETY'S COLLECTIVE INVE- STIGATION INTO THE USE OF ANTITOX- IN IN THE TREATMENT OF DIPHTHERIA IN PRIVATE PRACTICE.¹

THIS subject was chosen by the officers of the society for its eighth annual meeting, with the belief that a large amount of valuable experience not otherwise available might in this way be reached and collated. It was also believed that a more trustworthy estimate of the value of the serum treatment of diphtheria might thus be obtained than by statistics taken from hospital practice. There are very few hospitals in America that receive diphtheria patients, and the conditions under which patients are admitted to hospitals and the surroundings while there are so different from those of private practice, that the measure of success in hospital cases cannot be taken as an index of the results which have been obtained upon this side of the Atlantic with the new treatment.

In order, therefore, to obtain an expression of opinion from American physicians as to the serum treatment, after what had been, with most of them, their first year's experience, a circular letter was prepared and issued by the committee early in April. This was distributed through the members of the society as widely as could be done during the time allowed. An attempt was made to reach as many physicians as possible who had had experience with the remedy.

The first surprise of the committee was in learning how very widely the serum treatment had been employed, especially in the Eastern and mid-Western States. With more time the number of cases collected might easily have been doubled and perhaps trebled; but enough reports have come in to enable one to see what opinion was held on May 1, 1896, by American physicians who have used this remedy.

The circular letter asked for information upon the following points: Age; previous condition; duration of disease when the first injection was made; the number of injections; the extent of the membrane—tonsils, nose, pharynx, and larynx; whether or not the diagnosis was confirmed by culture; complications or sequelæ, viz., pneumonia, nephritis, sepsis, paralysis; the result; and remarks, including other treatment employed, the preparation of antitoxin used, and general impression drawn from the cases.

Reports were returned from six hundred and fifteen different physicians, with thirty-six hundred and twenty-eight cases. Of these, two hundred and forty-four cases have been excluded from our statistical tables. These were cases in which the disease was said to have been confined to the tonsils and the diagnosis not confirmed by culture, and therefore open to question. A few cases were reported in such doubtful terms as to leave the diagnosis uncertain. The figures herewith given are therefore made up from

cases in which the diagnosis was confirmed by culture (embracing about two-thirds of the whole number) and others giving pretty clear evidence of diphtheria, either in the fact that they had been contracted from other undoubted cases, or where the membrane had invaded other parts besides the tonsils, such as the palate, pharynx, nose, or larynx. It is possible that among the latter we have admitted some streptococcus cases, but the number of such is certainly very small.

There are left, then, of these cases, thirty-three hundred and eighty-four for analysis. These have been observed in the practice of six hundred and thirteen physicians from one hundred and fourteen cities and towns, in fifteen different States, the District of Columbia, and the Dominion of Canada.

In the general opinion of the reporters the type of diphtheria during the past year has not differed materially from that seen in previous years, so that it has been average diphtheria which has been treated. If there is any difference in the severity of the cases included in these reports from those of average diphtheria, it is that they embrace a rather larger proportion of very bad cases than are usually brought together in statistics. The cases, according to the extent of the membrane, are grouped as follows: In five hundred and ninety-three the tonsils alone were involved. In thirteen hundred and ninety-seven the tonsils and pharynx, the tonsils and nose, the pharynx and nose, or all three were affected. In twelve hundred and fifty-six cases the larynx was affected either alone or with the tonsils, pharynx, and nose, one or all. In many instances the statement is made by the reporters that the serum was resorted to only when the condition of the patient had become alarmingly worse under ordinary methods of treatment. This is shown by the unusually large number of cases in which injections were made late in the disease. Again, many physicians, being as yet in some dread of the unfavorable effects of the serum, have hesitated to use it in mild cases, and have given it only in those which from the onset gave evidence of being of a severe type. The expense of the serum has unquestionably deterred many from employing it in mild cases. These facts, it is believed, will more than outweigh the bias of any antitoxin enthusiasts by including many mild cases which would have recovered under any treatment. It will, however, be remembered that tonsillar cases not confirmed by culture have not been included.

Only two reports embracing a series of over one hundred cases have been received, most of the observers having sent in from five to twenty cases, although there are many reports of single cases, particularly of single fatal ones.

In addition to this material which has come in response to the circular, there have been placed at the disposal of the committee, by the courtesy of Dr. H. M. Biggs, nine hundred and forty-two cases treated in their homes in the tenements of New York. Of these, eight hundred and fifty-six were injected by the corps of inspectors of the New York health board, upon the request of the attending physician, and eighty-six others were treated by physicians receiving free antitoxin from the health board. In the first group the diagnosis of diphtheria was confirmed by culture in every

¹ Reported at the Eighth Annual Meeting, held at Montreal, Canada, May 26, 1896.

case, and in all of the latter except twenty-six; in these the diagnosis rested upon extensive membranous deposits or laryngeal invasion. The cases of the New York health board were of a more than ordinarily severe type, four hundred and eighty-five, or more than fifty per cent., of these being reported as being in bad condition at the time of injection; to mild cases the inspectors were not often called. Further, an unusually large number of them (thirty-eight per cent.) were injected on or after the fourth day of the disease. In one hundred and eighty-two of these cases only the tonsils were affected; in four hundred and sixty-six the tonsils with the pharynx or nose, the pharynx and nose, or all three; in two hundred and ninety-four the larynx was invaded either with or without disease of the tonsils, nose, or pharynx.

Through the courtesy of Dr. Biggs, the committee is able to include also a partial report upon fourteen hundred and sixty-eight cases from Chicago, treated in their homes in that city by a corps of inspectors of the health department. It was the custom in Chicago to send an inspector to every tenement-house case reported, and to administer the serum unless it was refused by the parents. These cases were therefore treated much earlier and the results were correspondingly better than were obtained in New York, although the serum used was the same in both cities, viz., that of the New York health board.

The Result as Influenced by the Time of Injection.—In Table I. are given the results obtained in these three different groups of cases, classified according to the day on which they received the first injection of serum antitoxin.

TABLE I.—DAY OF INJECTION AND RESULT.

	INJECTED ON FIRST DAY.			INJECTED ON SECOND DAY.			INJECTED ON THIRD DAY.			INJECTED ON FOURTH DAY.			INJECTED ON OR AFTER FIFTH DAY.			DAY OF INJECTION UNKNOWN.			TOTALS.		
	Cases.	Deaths.	Mortality, Per Cent.	Cases.	Deaths.	Mortality, Per Cent.	Cases.	Deaths.	Mortality, Per Cent.	Cases.	Deaths.	Mortality, Per Cent.	Cases.	Deaths.	Mortality, Per Cent.	Cases.	Deaths.	Mortality, Per Cent.	Cases.	Deaths.	Mortality, Per Cent.
Committee's report	764	38	4.9	1,065	89	8.3	620	79	12.7	336	77	22.9	390	152	38.9	215	15	7.0	3,384	450	13.0
New York health board	126	11	8.7	215	26	12.0	228	37	16.6	153	32	20.9	203	59	29.0	17	4	23.5	942	169	17.8
Chicago health board	106	0	0	336	5	1.5	660	18	2.7	269	38	14.1	97	33	34.0	0	0	0	1,468	94	6.4
Total	996	49	4.9	1,616	120	7.4	1,508	134	8.8	758	147	20.7	690	244	35.3	232	19	8.2	5,794	713	12.3

The grand total gives fifty-seven hundred and ninety-four cases with seven hundred and thirteen deaths, or a mortality of 12.3 per cent., including every case returned; but the reports show that two hundred and eighteen cases were moribund at the time of injection or died within twenty-four hours of the first injection. Should these be excluded there would remain fifty-five hundred and seventy-six cases (in which the serum may be said to have had a chance), with a mortality of 8.8 per cent.

Of the forty-one hundred and twenty cases injected during the first three days there were three hundred and three deaths—a mortality of 7.3 per cent., including every case returned. If from these we deduct the cases which were moribund at the time of injection, or which died within twenty-four hours, we have four thousand and thirteen cases, with a mortality of 4.8 per cent. Behring's original claim, that if cases were injected on the first or second day the mortality would not be five per cent., is more than substantiated by these figures. The good results obtained in third-day injections were a great surprise to your committee. But after three days have passed the mortality rises rapidly,

and does not differ materially from ordinary diphtheria statistics. Our figures emphasize the statement so often made, that relatively little benefit is seen from antitoxin after three days; however, it must be said that striking improvement has in some cases been seen even when the serum has been injected as late as the fifth or sixth day. The duration of the disease, therefore, is no contraindication to its use.

The Influence of Bacteriological Diagnosis upon the Statistics.—This is shown in Table II.

TABLE II.—DIAGNOSIS CONFIRMED BY BACTERIOLOGICAL EXAMINATION.

	Cases.	Deaths.	Mortality, Per Cent.
Committee's reports	2,453	302	12.3
New York board of health	916	160	16.9
Chicago board of health	1,468	94	6.4
Totals	4,837	556	11.4
Excluding 145 cases which were moribund or which died in twenty-four hours			8.7

DIAGNOSIS FROM CLINICAL EVIDENCE ONLY.

	Cases.	Deaths.	Mortality, Per Cent.
Committee's reports	931	148	15.7
New York board of health	26	9	34.6
Totals	957	157	16.3
Excluding 72 cases either moribund or dying in twenty-four hours			9.6

In the cases in which the diagnosis was not confirmed by a bacteriological examination the mortality is thus five per cent. higher than in the bacteriological cases. This difference is to be explained by two facts:

first, as already stated, that we have excluded from our reports all tonsillar cases (and hence most of the very mild ones) not confirmed by bacteriological examinations; and secondly, by the fact that this group of cases comprises those treated in the country, where physicians have hesitated to use antitoxin unless the type of the disease was a grave one, and where also a large proportion of the injections were made later than in the cities. However, should we leave out the moribund cases, the mortality is but 9.6 per cent., which differs but slightly from the cases confirmed by bacteriological diagnosis.

In our subsequent statistics we shall consider together all the cases bacteriologically confirmed and otherwise, as the statistics are not materially altered by this grouping.

The Results as Modified by the Age of the Patients.—Unfortunately, the ages have not been furnished in the report of the Chicago cases, and we have therefore only the cases reported to the committee and those from the New York board of health for analysis. In Table III. is shown the mortality of the different ages grouped separately.

TABLE III.—AGE AND RESULT OF TREATMENT.

	0 TO 2 YEARS.			2 TO 5 YEARS.			5 TO 10 YEARS.			10 TO 15 YEARS.			15 TO 20 YEARS.			20 YEARS AND OVER.

Totals.....	867	202	23.3	1,742	258	14.7	1,061	129	12.1	305	19	6.2	123	4	3.2	236	9	3.8
Moribund	43			59			59			9			0			4		
Mortality, excluding moribund cases.			19.2			13.3			8.7			3.3			3.2			2.1

The highest mortality is seen as in all reports to be in the cases under two years, but including all those returned, even those that were moribund when injected, the death rate was but 23.3 per cent. (21.7 per cent. of the committee's cases), while, if we exclude cases moribund when injected or dying within the first twenty-four hours, it falls to 19.2 per cent.

After the second year there is noticed a steady decline in mortality up to adult life. In many of the reports previously published the statement has been made that no striking improvement in results was observed in adult cases treated by the serum. Our figures strongly contradict this opinion. Of three hundred and fifty-nine cases over fifteen years old which were returned, there were but thirteen deaths. That the reader may judge for himself how far antitoxin is to be held responsible for the result, a brief summary of these thirteen cases is appended:

CASE I.—Fifteen years old; injected on the fourth day; membrane covering tonsils and pharynx; profoundly septic, sinking rapidly when injected; died in two hours. "My only death in seventeen cases" (Jones, Gloucester, Mass.).

CASE II.—Forty-four years old; injected on the fourth day; membrane on the tonsils and pharynx; in bad condition; died three hours after injection. The tonsils had been previously incised, the early diagnosis having been quinsy.

CASE III.—Thirty-one years old; injected on the sixth day; membrane on the tonsils, nose, pharynx, and larynx; intubation; sepsis; in bad condition; lived eight hours after injection.

CASE IV.—Thirty-five years old; injected on the fifth day; membrane on the pharynx and nose (?); in bad condition; septic; died in twelve hours.

CASE V.—Sixty years old; in bad condition; had serious mitral regurgitation; injected on the fourth day; membrane covering tonsils, pharynx, and larynx; died from heart failure on following day.

CASE VI.—Sixty years old; "kidney trouble for years;" injected on the third day; very extensive membrane, covering tonsils, pharynx, and nose; profound sepsis; in bad condition; died suddenly on the day after injection.

CASE VII.—Seventeen years old; in bad condition; convalescing from measles; enormous adenopathy; profound sepsis; exceedingly high temperature; membrane covering tonsils and nose; injected at the end of forty-eight hours; three injections, temporary improvement after each one; duration of life not given.

CASE VIII.—Fifteen years old; in bad condition; injected on the ninth day; membrane covering tonsils, nose, pharynx, and larynx; no operation; enormous infiltration of the tissues of the neck; nephritis; sepsis; lived four days and died of sepsis.

CASE IX.—Twenty years old; injected on the third

day; membrane upon the tonsils, nose, pharynx, and larynx. "A stubborn patient, who got up before he was allowed, and died suddenly after it."

CASE X.—Twenty-five years old; injected on the fifth day; membrane covering both tonsils, entire pharynx, and completely occluding nose; nephritis and sepsis; throat cleared off entirely; died suddenly on the fourteenth day from cardiac paralysis.

CASE XI.—Nineteen years old; injected on the fifth day; membrane upon the tonsils and pharynx; profound sepsis; duration of life unknown.

CASE XII.—Twenty-two years old; injected on the fourth day; membrane on the tonsils and gums; sepsis; died on the sixth day.

CASE XIII.—The well-known Brooklyn case, reported in 1895. Girl, sixteen years old, who died suddenly ten minutes after injection.

Such are the adult cases which antitoxin failed to cure. Four of them were moribund at the time of injection, no one of them living over twelve hours. Two, both sixty years old, were already crippled by previous organic disease, one of the heart and the other of the kidneys. In the measles case there was undoubted evidence of streptococcus septicæmia. Only two of the cases were injected as early as the third day, three of them on the fifth day, and one on the ninth day. Omitting the four moribund cases, the mortality of three hundred and fifty-five adult cases treated with the serum is 2.5 per cent.

Paralysis.—Reliable data upon this point and those hereafter to be mentioned are to be had only from the thirty-three hundred and eighty-four reports returned to the committee. Of these, paralytic sequelæ appeared in three hundred and twenty-eight cases, 9.7 per cent. Of the twenty-nine hundred and thirty-four cases which recovered, paralysis was present in two hundred and seventy-six, or 9.4 per cent. Of the four hundred and fifty cases which died, paralysis was noted in fifty-two, or 11.4 per cent.

Observations of some of the individual cases are interesting, particularly those of cardiac paralysis. It is twice stated that the child had gotten up and walked out of the house, where it was found dead. Twice death occurred after sitting up suddenly; once, on jumping from one bed to another. One patient of twenty years got up contrary to orders and died soon afterward. Another patient was apparently well until he indulged in a large quantity of cake and candy, soon after which cardiac symptoms developed, and he died shortly. One case was that of a woman sixty years old, who had serious organic cardiac disease.

It is difficult from these statistics to state what protective power the serum may have over the nerve cells and fibres. Apparently this is not great unless the injections are made early in the disease, and even then in severe cases the amount of damage done to these tissues in twenty-four hours may be very great, even

irreparable. Time is not the only element in estimating the effect of the diphtheria toxins.

Great discrepancy exists in the statements made regarding the frequency of paralytic sequelæ after diphtheria. In a series of one thousand cases reported by Lennox Browne, paralytic sequelæ were present in fourteen per cent. In twenty-four hundred and forty-eight cases by Sanné, paralysis was noted in eleven per cent. In the series of cases here reported, the difference is slightly in favor of the antitoxin treatment, but paralysis is certainly frequent enough to show how extremely susceptible the nervous elements are to the diphtheria toxins. One thing is quite striking from a study of these cases, and that is the proportion that have died from late cardiac paralysis. That very many of them would undoubtedly have succumbed earlier in the disease from suffocation (laryngeal cases) or diphtheritic toxæmia, had the serum not been employed, is beyond question. Although the serum is able to rescue even many such desperate cases, it cannot overcome the effects of the toxins upon the cells which have occurred before it was injected.

The variety of the paralysis and the date of injection is shown in the following table:

TABLE IV.—VARIETY OF PARALYSIS AND THE DAY OF INJECTION.

RECOVERY CASES.	Cases.	DAY OF INJECTION.				
		1st Day.	2d Day.	3d Day.	4th Day.	5th Day.
Paralysis mentioned (variety not specified).	132	5	32	32	19	16

Sepsis.—Sepsis is stated to have been present in three hundred and sixty-two of the thirty-three hundred and eighty-four cases, or 10.7 per cent. It was present in one hundred and forty-five, or thirty-three per cent., of the fatal cases. Some explanation is necessary for a correct appreciation of these figures. The majority of the reporters, it is plain from their remarks, have not distinguished between diphtheritic toxæmia and streptococcus sepsis. The former is certainly meant in the great majority of the cases. There is a very small proportion in which there is evidence of streptococcus sepsis. The six cases complicating measles, and the five complicating scarlet fever, however, should possibly be included in this list.

Nephritis.—The statements on this point are quite unsatisfactory. The reports state that nephritis was present three hundred and fifty times, or in ten per cent. of the cases. On the one hand, it must be stated that the diagnosis of nephritis rests in many cases simply upon the presence of albumin in the urine; but, on the other hand, it is true that in a large number of the cases, more than half, no examination of the urine is recorded as having been made, so that it is impossible to state, with anything like approximate accuracy, the frequency of nephritis in these cases.

¹ Cases of heart failure occurring at the height of the disease have not been included here, although they are mentioned among the cases of cardiac paralysis in the table of fatal cases.

Of the four hundred and fifty fatal cases, the presence of nephritis is mentioned without qualification or explanation in thirty-nine cases; these being usually put down also as septic, dying in the acute stage of the disease. There are fifteen fatal cases, however, in which the renal disease was stated as the cause of death. In no less than nine the nephritis occurred late in the disease, usually during the second or third week. In these fifteen cases the evidence of severe nephritis was conclusive, such symptoms being present as dropsy, suppression of urine, with coma or convulsions.

Broncho-Pneumonia.—Broncho-pneumonia is stated to have been present in one hundred and ninety-three of the thirty-three hundred and eighty-four cases, or 5.9 per cent., a remarkably small proportion when compared with hospital statistics. Among the patients that recovered, broncho-pneumonia was noted one hundred and fourteen times, or in 3.8 per cent.; among the fatal cases seventy-nine times, or in 17.5 per cent., but in only about half of these was the pneumonia the cause of death. Of these, thirty-seven were laryngeal cases operated upon late, ten were septic cases, and the pulmonary disease was coincident with the height of the diphtheritic process. In seven pneumonia was independent of both the above conditions, occurring late in the disease in all but two.

Laryngeal Cases.—Of the thirty-three hundred and eighty-four cases reported to the committee, the larynx is stated to have been involved in twelve hundred and fifty-six cases, or 37.5 per cent. This proportion is somewhat higher than is usual, and is partly explained by the fact that several physicians have sent in the reports only of their laryngeal cases. These laryngeal cases occurred in the practice of three hundred and seventy-nine physicians.

In six hundred and ninety-one, or a little more than one-half the number, no operation was done, and in this group there were one hundred and twenty-eight deaths. In forty-eight of them laryngeal obstruction was responsible for the fatal issue, operation being refused by the parents, or no reason for its being neglected having been given. In the eighty remaining fatal cases the patients died of other complications, and not from the laryngeal disease.

In the five hundred and sixty-three cases, therefore, or 16.9 per cent. of the whole number, there was clinical evidence that the larynx was involved, and yet recovery took place without operation. In many of these cases the symptoms of stenosis were severe, and yet disappeared after injection without intubation. No one feature of the cases of diphtheria treated by antitoxin has excited more surprise among the physicians who have reported them than the prompt arrest, by the timely administration of the serum, of membrane which was rapidly spreading downward below the larynx. Such expressions abound in the reports as "wonderful," "marvellous," "prepared to do intubation, but at my next visit the patient was so much better it was unnecessary," "in all my experience with diphtheria have never seen anything like it before," "no unprejudiced mind could see such effects and not be convinced of the value of the serum," etc.

In establishing the value of the serum, nothing has been so convincing as the ability of antitoxin, properly administered, to check the rapid spreading of membrane downward in the respiratory tract, as is attested by the observations of more than three hundred and fifty physicians who have sent in reports.

Turning now to the operative cases, we find the same remarkable effects of the antitoxin noticeable. Operations were done in five hundred and sixty-five cases, or in 16.7 per cent. of the entire number reported. Intubation was performed five hundred and thirty-three times, with one hundred and thirty-eight deaths, or a mortality of 25.9 per cent. In the above

are included nine cases in which a secondary tracheotomy was done, with seven deaths. In thirty-two tracheotomy only was done, with twelve deaths, a mortality of 37.4 per cent. Of the five hundred and sixty-five operative cases, sixty-six were either moribund at the time of operation or died within twenty-four hours after injection. Should these be deducted, there remain four hundred and ninety-nine cases operated upon by intubation or tracheotomy, with eighty-four deaths, a mortality of 16.9 per cent.

Of the twenty-eight hundred and nineteen cases not operated upon, there were three hundred and twelve deaths, a mortality of 11.3 per cent. Deducting the moribund cases or those dying within twenty-four hours after injection, the total mortality of all non-operative cases was 9.12 per cent.

Let us compare the results of intubation in cases in which the serum was used with those obtained with this operation before the serum was introduced. Of fifty-five hundred and forty-six intubation cases in the practice of two hundred and forty-two physicians, collected by McNaughton and Maddren (1892), the mortality was 69.5 per cent. Since that time statistics have improved materially by the general use (in and about New York, at least) of calomel fumigations. With this addition, the best results published (those of Brown) showed in two hundred and seventy-nine cases a mortality of 51.6 per cent.

Let us put beside the cases of McNaughton and Maddren the five hundred and thirty-three intubations with antitoxin, with 25.9 per cent. mortality. With Brown's personal cases let us compare those of the fourteen observers who have reported to the committee ten or more intubation operations in cases injected with serum. These comprise two hundred and eighty cases with sixty-five deaths, a mortality of 23.2 per cent. In both comparisons the mortality without the serum is more than twice as great as in the cases in which serum was used.

The reports of some individual observers concerning intubation with the serum are interesting:

Neff, New York: Twenty-seven operations, with twenty-seven recoveries.

Rosenthal, Philadelphia: Eighteen operations, with sixteen recoveries.

Booker, Baltimore: Seventeen operations, with seventeen recoveries, including one aged ten months, and one seven and one-half months.

Seward, New York: Eight operations, with eight recoveries.

McNaughton, Brooklyn: "In my last seventy-two operations without serum, mortality 66.6 per cent.; in my first seventy-two operations with serum, mortality 33.3 per cent."

O'Dwyer, New York: "In my last one hundred intubations, first seventy without serum, mortality seventy-three per cent.; last thirty with serum, mortality 33.3 per cent."

But even these figures do not adequately express the benefit of antitoxin in laryngeal cases. Witness the fact that over one-half the laryngeal cases did not require operation at all. Formerly, ten per cent. of recoveries was the record for laryngeal cases not operated upon. Surely, if it does nothing else, the serum saves at least double the number of cases of laryngeal diphtheria that has been saved by any other method of treatment.

The great preponderance of intubation over tracheotomy operations shows how much more highly the profession in this country esteems the former operation.

A Study of the Fatal Cases.—Of the four hundred and fifty fatal cases in the committee's report, two hundred and twenty-nine, or one-half, received their first injection of the serum on or after the fourth

day of the disease, and one hundred and fifty-two, or over one-third of these, on or after the fifth day.

There were fifty-eight cases in which it was stated that the child was moribund at the time of injection, the serum being administered without the slightest expectation of benefit, but at the earnest solicitation of the parents.

There remain three hundred and fifty cases in which the cause of death could be pretty accurately determined by the reports. These died from the following causes, the most important cause being placed first:

Sepsis (including diphtheritic toxæmia) was the cause of death in one hundred and five cases: of which sixteen had nephritis, four were intubated or tracheotomized, two were laryngeal cases not operated upon, four had paralysis, one had pneumonia, and in one the fatal sepsis was attributed to a traumatic condition of the left knee.

Cardiac paralysis was the cause of death in fifty-three cases. Under this head are included cases of sudden heart failure occurring at the height of the disease (twenty-one in number), as well as those more commonly designated as heart paralysis, where death occurred suddenly after the throat cleared off. Of the latter there were thirty-two examples; four of these cases had throat paralysis, nineteen were septic, eight had nephritis, five were intubated, and one tracheotomized.

Broncho-pneumonia was put down as the cause of death in fifty-four cases. In thirty-seven of these it followed laryngeal diphtheria; of these, twenty-two were intubated and four tracheotomized; two had nephritis; nine were septic. Broncho-pneumonia and sepsis was the cause of death in ten cases, of which three had nephritis and one general paralysis. Broncho-pneumonia caused death in seven cases, apart from sepsis or laryngeal diphtheria; of these, only one had nephritis; one died from heart failure; and in five pneumonia came on late in the disease.

Laryngeal diphtheria without operation caused death in forty-eight cases. In some of these the operation was refused by the parents, in others it was neglected by the physician, the patients dying of asphyxia; three of these cases had nephritis, four were septic, two had pneumonia, and one had sepsis and nephritis.

Diphtheritic tracheitis or bronchitis caused death in eleven cases; all of these were intubated, and in two there was evidence of the existence of membrane in the bronchi before operation. There were thirty-three other cases in which death followed laryngeal diphtheria without the supervention of pneumonia. It is highly probable that in some of these death was due to membranous tracheitis or bronchitis. All of them were operated upon: ten were septic, two had paralysis, and one had nephritis.

Sudden obstruction of the intubation tube was the cause of death in three other laryngeal cases.

The tube was coughed up in three cases, fatal asphyxia occurring before the physician could be summoned.

Died on the table during tracheotomy, one case.

Nephritis was the cause of death in fifteen cases; seven of these were septic and three had been intubated.

General paralysis was the cause of death in five cases; in all probably the pneumogastric was involved.

Paralysis of the respiratory muscles produced death in one case, one of laryngeal diphtheria, which was intubated and was complicated by broncho-pneumonia.

Measles associated with diphtheria produced death in six cases; five of these were laryngeal and were intubated; in two there was pneumonia and in two sepsis. Diphtheria developed during the height of the measles or immediately followed it.

Scarlet fever with diphtheria was the cause of death

in six cases; in three of these there was bronchopneumonia, nephritis, and sepsis; in two scarlet fever preceded diphtheria, and in one of these there was sepsis with gangrene of the tonsils. In the sixth case the patient died of scarlet fever, which developed during convalescence from the diphtheria.

Gangrene of the cervical glands or cellular tissue of the neck was the cause of death in two cases associated with profound general sepsis.

Endocarditis caused death in one case, nineteen days after the diphtheria.

Diphtheritic inflammation of the tracheal wound with sepsis caused death in one case.

General tuberculosis, five weeks after diphtheria, was assigned as the cause of death in one case.

Exhaustion was the cause of death in three cases, one a protracted case; another complicated by pneumonia and sepsis; one by nephritis.

Convulsions was the cause of death in three cases apart from disease of the kidneys. In one, the well-known Brooklyn case, the girl died ten minutes after the injection, in another twenty-four hours after injection, in the third the particulars were not given.

Meningitis was assigned as the cause of death in one case.

The Kind of Antitoxin Used.—They are given in the order of frequency with which they have been used. First, the serum prepared by the New York board of health; second, Behring's; third, Gibier's;¹ fourth, Mulford's; fifth, Aronson's; sixth, Roux's. In addition, a large number of cases are reported as having been treated by the serum prepared by the health boards of different cities—Brooklyn, Newark, Rochester, Pittsburg, etc. The largest number of cases have been treated by the serum prepared by the New York health board, a very large number by Behring's serum, all others being relatively in small numbers.

Dosage and Number of Injections.—In the great majority of cases but one injection is reported. In very severe ones two and three have been given. The largest amount is in a case by Weimer (Chicago) who gave eighteen injections of Behring's serum to a laryngeal case in a child thirteen years old. Another instance of ten injections is reported with no unfavorable symptoms.

As a rule the dosage has been smaller in antitoxin units than is now considered advisable, particularly in many of the laryngeal cases and others injected later than the second day.

Cases Injected Reasonably Early (During the First Three Days) in which Antitoxin is Said to have Produced no Effect, the Disease Ending Fatally.—These cases are nineteen in number. Brief reports are introduced that the reader may judge to what degree they may be regarded as a test of the serum treatment. In our statistical tables all of them have been included among the fatal cases.

In Cases I. and II. the cultures were reported negative.

CASE I., by Gallagher, New York: Child eighteen months old; septic; although no eruption was present, the reporter was "inclined on reflection to regard this case as one of scarlatinal sore throat."

CASE II., by Potter, Buffalo: Male, fourteen months old; two cultures made, but no Loeffler bacilli found; membrane in the nose and pharynx. Injected on the third day, one dose of Behring's serum No. 1. No improvement; death from sepsis. "Probably pseudo-diphtheria" (I. H. P.).

¹ It is worthy of note that in the tests made by the State Board of Health of Massachusetts, published under date of April 6, 1896, this serum was found far below the standard as labelled upon the bottle; thus, a package marked to contain twenty-five hundred units, by test was found to contain less than seven hundred. All the other varieties of serum tested were found essentially up to the standard.

In Cases III. to IX. no cultures were made.

CASE III., by Tefft, New Rochelle: Seven years old; injected after eighteen hours' illness; two injections of Behring's No. 2 serum: membrane on the tonsils, pharynx, and nose; no effect observed from injections, patient dying on the third day.

CASE IV., by Tefft: Male, four years old; membrane on the tonsils and pharynx: injected after thirty-six hours' illness with Behring's No. 2; died on the third day; no noticeable effect from the injection.

CASE V., by Tefft: Six years old; membrane on the tonsils, nose, and pharynx; septic; injected after thirty-six hours' illness; three injections of Behring's No. 2. "Saw no effect from the injections, the disease going steadily on to a fatal termination."

CASE VI., by Cameron, Montreal: Two and a half years old; fifty hours ill; membrane on the tonsils, nose, and pharynx; septic; no improvement noticed, and child died twenty hours after injection.

CASE VII., by Baker, Newtonville, Mass.: Three years old; laryngeal diphtheria; injected on the third day ten cubic centimetres Roux's serum: cyanosis; intubation; temperature 103° F., and continued high until death in eighteen hours after operation; injections had no effect.

CASE VIII., by Anderson, New York: Three years old; injected after three hours' illness; membrane on the tonsils, nose, and pharynx; one injection of New York health board antitoxin. "A case of malignant diphtheria, full duration twenty-four hours."

CASE IX., by McLain, Washington: Four years old; twelve hours sick; membrane on the pharynx and larynx; two injections; no operation; first injection early in the morning, the other early in the afternoon; died the same day; no change in the condition; antitoxin had no apparent effect.

In Cases X. to XIII. diphtheria complicated measles, all reported by W. T. Alexander, New York. Disease confined to the larynx in all; in three the stenosis developed during measles, and in one while the patient was convalescing from measles; diagnosis confirmed by culture in every case, and in all intubation performed. Antitoxin seemed to have no effect, the cases going on to a fatal termination; all received their injections within twenty-four hours after the laryngeal symptoms appeared.

In three cases—XIV. to XVI.—the type of the disease was malignant from the outset.

CASE XIV., by Lloyd, Philadelphia: Fifteen months old; injected after thirty-six hours' illness; diagnosis confirmed by culture; membrane covered the tonsils, pharynx, nose, and larynx; intubation; sepsis; death on the fifth day. Although antitoxin was used as promptly as possible no perceptible effect was noticed. One injection, Behring's No. 3, was given.

CASE XV., by Wert, Mount Vernon, N. Y.: Eighteen months old; injected on the third day; diagnosis confirmed by culture; membrane on the tonsils and pharynx. "Very intense type of the disease." Antitoxin could not be procured before the third day; Gibier's serum used. "Died suddenly in apparent convulsions about ten hours after injection; urine not examined; very little passed."

CASE XVI., by Ingraham: Six years old; membrane covered the tonsils, pharynx, and larynx; diagnosis confirmed by culture; pneumonia present; condition very bad; injected after two and a half days' illness; three injections of Behring's serum; no benefit noticed.

CASE XVII., by Johnson, Buffalo: Three years old; twelve hours ill; case septic from the start; membrane on the tonsils, pharynx, and larynx; diagnosis confirmed by culture. "Antitoxin apparently had very little effect."

CASE XVIII., by Baker, Newtonville, Mass.: Two and a half years old; twenty hours ill; disease confined to larynx; diagnosis confirmed by culture; one injection of Gibier's serum; intubation. "Was doing well a few minutes before death, when child got up in its crib, changed color, and died almost immediately." Death attributed to "sudden heart failure; found no obstruction of the tube."

CASE XIX., by Story, Washington: Five years old; in fair condition; thirty-six hours ill; diagnosis confirmed by culture; membrane on the tonsils, pharynx and larynx; one injection of United States Marine Hospital antitoxin; injection produced no effect.

Cases in which Unfavorable Symptoms Were, Might Have Been, or Were Believed to Have Been, Due to Antitoxin Injections.—Only three cases reported to the committee could by any possibility be placed in this category. All of the details furnished by the reporters are reproduced:

CASE I., by Kortright, Brooklyn: Sudden death in convulsions ten minutes after injection. This case is the already well-known Valentine case, occurring in Brooklyn in the spring of 1895. The principal points were as follows: A girl sixteen years old; in good condition; tonsillar diphtheria; diagnosis confirmed by culture; injected on the first day with ten cubic centimetres of Behring's serum; died in convulsions ten minutes later.

CASE II., by Kerley, New York: Fairly healthy boy, two and one-half years old; membrane on tonsils, pharynx, and in nose. Diagnosis confirmed by culture; injected on the morning of the fourth day with ten cubic centimetres (1,000 units) New York health board serum; temperature at time of injection 100.4° F.; no sepsis, and child apparently not very sick; urine free from albumin. Distinctly worse after injection; in ten hours temperature rose to 103° F.; urine albuminous; throat cleared off rapidly, but marked prostration and great anæmia, with irregular fluctuating temperature, continued, and death followed from exhaustion with heart failure four days after the use of the serum.

CASE III., by Eynon, New York: Male, three and one-half years old; diagnosis confirmed by culture; two days ill; membrane on tonsils and in nose; two injections New York health board serum. "A rapid nephritis developed after the second injection, causing coma, convulsions, and death twenty hours after the second injection." In response to an inquiry for further particulars the following was received: "The case seemed a mild one, but the injection was given one afternoon and repeated the following afternoon, about 1,500 units in all. The urine up to that time had not been examined. About four or sixteen hours after the second injection unfavorable symptoms began to develop, pointing to infection of the kidneys. The urine was found to be loaded with albumin. My impression at the time was that the antitoxin either produced, hastened, or intensified nephritis, thereby causing the fatal termination."

In regard to the three fatal cases just cited, Case I. is wholly unexplained. In Case II. the query arises, did this sudden change hinge upon the injection of the serum, or was it one of those unexplained abrupt changes for the worse in a case apparently progressing favorably, so often observed in diphtheria? As regards Case III., it will be seen from the letter that the evidence is not at all conclusive. All details available are given, and the reader may draw his own conclusions.

Clinical Comments.—The following are selected from hundreds which have been received, and may be taken fairly to represent the sentiments of the physicians who have sent in reports:

Dr. Douglas H. Stewart, New York, sends reports of four cases, all desperate ones, and all "presumably

fatal under any other form of treatment." Very extensive membrane in all: larynx involved in three; in one neglected case in a child three years old, injected upon the fifth day, the membrane covered the tonsils, nose, pharynx, and larynx. Broncho-pneumonia, nephritis, and sepsis all present. Temperature 107° F. at the time of the first injection. Prostration so great that he dared not attempt intubation. Believes that this case would certainly have been fatal in a few hours without antitoxin. Perfect recovery.

In another case, three years old, membrane first discovered in the left ear; next morning seen upon the tonsils; spread in a few hours over the pharynx into the larynx and trachea. Intubation necessary in a few hours; had never seen membrane spread so rapidly as in this child. Urine albuminous; membrane subsequently expelled from larynx and trachea in large casts, with profuse bloody expectoration. Complete recovery on the ninth day. The physician describes this as "the very worst case of diphtheria that has ever come under my notice." Fifty-four hundred antitoxin units were given in four injections. He remarks: "My experiences in the past have been so very unfortunate that the advocates of antiseptics or therapeutics were a constant surprise to me. It has been my fate to have the most desperate cases unloaded upon my shoulders. I have been forced into the belief that the profession was absolutely powerless in the presence of true diphtheria; have lost case after case with tube in the larynx and calomel fumigations at work. Previous to antitoxin my only hope had become centred in nature and stimulants. In two years I have not lost a single case, and surely I may be pardoned if I suffer from diphtheria-phobia in a sub-acute form, and use antitoxin sometimes unnecessarily."

Dr. L. L. Danforth, New York, states that during his twenty-two years of practice in New York he had seen many fatal cases of diphtheria, had used all kinds of remedies, mainly those of the homeopathic school, and while he had as much confidence in the latter as in anything else, he had seen so many deaths during the year past that he "hailed with delight the advent of antitoxin, and determined to use it." Reports five cases, all of a severe type. "The result in every case has been marvellous. I would not dare to treat a case now without antitoxin."

Dr. H. W. Berg, New York, reporting fourteen cases, says: "I have not yet ceased to be surprised at the recovery of some of these cases, which, in the light of my former experience with diphtheria treated without antitoxin, seemed to be irretrievably lost."

Dr. George McNaughton, Brooklyn, reports seventy-two laryngeal cases, with twenty-four deaths; sixty-seven of these were intubated, with twenty-one deaths. He states that he has kept no records of cases other than laryngeal ones, as these seemed the best test of the serum treatment. He believes that if the serum is used early, very many cases will not need operation for the relief of stenosis. "I would urge the use of antitoxin in all cases of croup in any patient who has had an exudation upon the pharynx: would not wait for bacteriological confirmation of diagnosis, for in so doing valuable time is lost." Has noticed that the tube is coughed up more frequently in injected cases, and believes this due to the fact that the swelling of the tissues subsides at an earlier date.

Dr. D. C. Moriarta, Saratoga, reporting four cases, says that the first was a malignant one, and "I only used the remedy because I am health officer and was urged to do so, as the type of the disease was that form which I have seen recover but once in eleven years." Boy five years old, four days ill when injected; great prostration, rapid breathing, and he was "practically gone." Nares filled and tonsils and pharynx

covered; severe nasal hemorrhage; cervical glands greatly swollen; heart's action very frequent and feeble; child unable to lie down. Behring's serum, twenty cubic centimetres injected; in six hours evidently more comfortable; in eighteen hours decidedly improved; in twenty-four hours sitting up and feeling much better; in forty-eight hours all urgent symptoms gone and membrane loosening. Subsequently had nephritis, which lasted six weeks, and multiple neuritis, which persisted for three months, but ultimately recovered perfectly. "I send this report because it converted me. No unbiassed person familiar with diphtheria could see such results as this and not feel there must be good in it."

Dr. F. M. Crandall, New York, sends report of a child seven years old. Membrane on the tonsils and in larynx, with croup for forty hours when antitoxin was injected and intubation done. Progress of the disease had been rapid; semi-stupor and eyes half open; very feeble rapid pulse; intense toxæmia; general cyanosis. Both cyanosis and dyspnoea persisted after intubation, showing clearly the presence of membrane below the tube. Case regarded as "absolutely hopeless." The first change was seen in the disappearance of toxæmia, with improvement in the pulse, clearness of the mind, etc.; later a change in the local condition; large masses of membrane were expelled from the larynx and trachea, necessitating frequent removals of the tube. Tube finally removed in a week with complete recovery.

Dr. Reynolds, Baltimore, mentions a case showing the danger of relying too implicitly upon the bacteriological diagnosis. Male, three years. Culture reported only staphylococcus and streptococcus, consequently injection delayed until the fifth day, when membrane covered tonsils, nose, and pharynx. Child died two days later. A sister subsequently contracted the disease, received antitoxin on the third day, and recovered. The reporter would not wholly rely upon the culture test for diagnosis.

Summary.—(1) The report includes returns from six hundred and fifteen physicians. Of this number more than six hundred have pronounced themselves as strongly in favor of the serum treatment, the great majority being enthusiastic in its advocacy.

(2) The cases included have been drawn from localities widely separated from each other, so that any peculiarity of local conditions to which might be ascribed the favorable reports must be excluded.

(3) The report includes the record of every case returned except those in which the evidence of diphtheria was clearly questionable. It will be noted that doubtful cases which recovered have been excluded, while doubtful cases which were fatal have been included.

(4) No new cases of sudden death immediately after injection have been returned.

(5) The number of cases injected reasonably early in which the serum appeared not to influence the progress of the disease was but nineteen, these being made up of nine cases of somewhat doubtful diagnosis; four cases of diphtheria complicating measles, and three malignant cases in which the progress was so rapid that the cases had passed beyond any reasonable prospect of recovery before the serum was used. In two of these the serum was of uncertain strength and of doubtful value.

(6) The number of cases in which the patients appeared to have been made worse by serum were three, and among these there is only one new case in which the result may fairly be attributed to the injection.

(7) The general mortality in the fifty-seven hundred and ninety-four cases reported was 12.3 per cent.; excluding the cases moribund at the time of injection or dying within twenty-four hours, it was 8.8 per cent.

(8) The most striking improvement was seen in the cases injected during the first three days. Of forty-one hundred and twenty such cases the mortality was 7.3 per cent.; excluding cases moribund at the time of injection or dying within twenty-four hours, it was 4.8 per cent.

(9) The mortality of fourteen hundred and forty-eight cases injected on or after the fourth day was 27 per cent.

(10) The most convincing argument, and to the minds of the committee an absolutely unanswerable one, in favor of serum therapy is found in the results obtained in the twelve hundred and fifty-six laryngeal cases (membranous croup). In one-half of these recovery took place without operation, in a large proportion of which the symptoms of stenosis were severe. Of the five hundred and thirty-three cases in which intubation was performed the mortality was 25.9 per cent., or less than half as great as has ever been reported by any other method of treatment.

(11) The proportion of cases of broncho-pneumonia—5.9 per cent.—is very small and in striking contrast to results published from hospital sources.

(12) As against the two or three instances in which the serum is believed to have acted unfavorably upon the heart, might be cited a large number in which there was a distinct improvement in the heart's action after the serum was injected.

(13) There is very little, if any, evidence to show that nephritis was caused in any case by the injection of serum. The number of cases of genuine nephritis is remarkably small, the deaths from that source numbering but fifteen.

(14) The effect of the serum on the nervous system is less marked than upon any other part of the body, paralytic sequelæ being recorded in 9.7 per cent. of the cases, the reports going to show that the protection afforded by the serum is not great unless injections are made very early.

The committee feels that this has been such a responsible task that it has thought best to state the principle which has guided it in making up the returns. While it has endeavored to present the favorable results with judicial fairness, it has also tried to give equal or even greater prominence to cases unfavorable to antitoxin.

In conclusion the committee desires in behalf of the society to express its thanks to members of the profession who have co-operated so actively in this investigation, and to Dr. A. R. Guerard for the preparation of the statistical tables.

SAMUEL S. ADAMS, M.D.,	

The Action of the Society upon the Report.—

At the close of its presentation, the society voted to accept the report of the committee, and after a full discussion it was decided to embody its conclusions in the following resolutions:

(1) Dosage. For a child over two years old, the dosage of antitoxin should be in all laryngeal cases with stenosis, and in all other severe cases, fifteen hundred to two thousand units for the first injection, to be repeated in from eighteen to twenty-four hours if there is no improvement; a third dose after a similar interval if necessary. For severe cases in children under two years, and for mild cases over that age the initial dose should be one thousand units, to be repeated as above if necessary; a second dose is not usually required. The dosage should always be estimated in antitoxin units and not of the amount of serum.

(2) Quality of antitoxin. The most concentrated strength of an absolutely reliable preparation.

(3) Time of administration. Antitoxin should be administered as early as possible on a clinical diagnosis, not waiting for a bacteriological culture. However late the first observation is made, an injection should be given unless the progress of the case is favorable and satisfactory.

The committee was appointed to continue its work for another year and was requested to issue another circular asking for the further co-operation of the profession, this circular to be sent out as soon as possible in order that physicians may record their cases as they occur through the coming year.

THE "X" RAY AND SOME OF ITS APPLICATIONS IN MEDICINE—DEMONSTRATIONS OF APPARATUS AT WORK AND EXHIBITION OF STEREOPTICON VIEWS.¹

BY WILLIAM J. MORTON, M.D.,

NEW YORK.

PHYSICIANS, from time immemorial, have ever had a keen desire to explore the interior of the animal body. Hence arose dissection, and later on vivisection, and still later on the revelations of the microscope. But none of these methods fully satisfy the wish to know what is actually taking place within the animal organism during life, particularly when the processes of life pursue a morbid course. Hence sprang up further methods of exploration, some of them optical, and some auditory, and many tactile.

These methods we need scarcely enumerate; familiar examples are the ophthalmoscope, the cystoscope, the instruments and methods for transillumination and for auscultation and percussion, the probe, simple and electrical. The standard resources of physical science have ever been applied by the physician to this aim, namely, exploration; each discovery as it is announced is eagerly scanned to see if it may not have some practical application toward this same end. And in reality it is a noble strife, for it represents not alone the practical desire of the physician to solve the problem of life and disease and death, but also that instinctive desire of the intelligent part of the human race to get closer to and learn more of the mystery of its own existence and thus to form some conception of immortality.

No wonder then that the "X" ray with its marvellous revelations of the hitherto unseen has excited a universal interest. Thus far its greatest promise of usefulness is to medicine and surgery. It behooves us, then, as physicians to familiarize ourselves with the new method of exploration, and, now that the first glare of its announcement and of its workings has subsided, to judiciously and conservatively turn our attention to its relations to medical and surgical practice.

Even as yet, in the undeveloped stage of Roentgen's discovery, there can be little doubt that no more valuable means of diagnosis has ever been afforded to medicine.

Historical.—It is not here the place or time to review the purely physical steps which led in direct succession up to Professor Roentgen's discovery. The nature of the "X" ray is not known. The very word ray and the idea of a radiation are as yet hypothetical, and meanwhile the entire scientific world is bending its energies to the solution of the problem. Happy the discoverer.

¹ Address at a stated meeting of the Medical Society of the County of New York, April 27, 1896.

The view that the effects, which we may term Roentgen effects, are due to a stream of electrified particles moving at a high rate of speed is easy of conception. The contending view, that we have to deal with disturbance of the ether, either transversal or longitudinal, falls into line with the beliefs and the kindred demonstrations of some of the greatest of modern thinkers. We of the medical profession may well leave this battle royal of the scientists to themselves, and while awaiting its issue turn our attention to the practical applications of the "X" ray.

Discarding theory, it is enough to state that from a high vacuum tube, commonly called a "Crookes" tube, emanates a "radiation" which passes through substance in direct ratio to the density of the substance, and is capable of recording its impact upon a fluorescent screen or upon a photographic sensitized plate or film. The picture is therefore a record of variations in density or, what is the same thing, a record of opacity of the various forms of matter submitted to the "X" ray. That, for this reason, the bones are outlined within the flesh is now a familiar story. But, in my own experience, an examination of my negatives proves that the differentiation of tissue by relative density is capable of being carried to a much greater refinement. In one and the same negative to-night I shall be able to show you at the same moment a picture of the medullary and cancellous cavities of the bones of the leg, of the tendons, of the muscles, and of the skin.

We will now examine

I. Apparatus and outfit.

II. Demonstrate its workings.

III. Exhibit products of its work (lantern slides).

I. [Here followed a description of the Ruhmkorff coil and Crookes tubes and an exhibition of the methods of using them.]

II. The record made by the "X" ray after its passage through substances of varying density may be obtained in two ways: the one the fluoroscopic, the other the radiographic.

(a) **Fluoroscopy.**—Roentgen himself pointed out the effect of the "X" ray upon fluorescent screens. Its development into its present practical form is due largely to the efforts of Mr. Edison, who early abandoned the photographic method in favor of the fluoroscopic and devoted himself to finding, first a highly sensitive fluorescent material and, second, a practical method of employing it. As is well known, Mr. Edison believes that the fluoroscopic method may be made of great practical value to medicine, and has devised a specially constructed apparatus for physicians' use. The essential features of his plan I hope to be able to demonstrate to you to-night through Mr. Edison's courtesy in extending every aid in his power to us, and through the courtesy of Messrs. Aylesworth and Jackson, who have put at my disposal this large screen of tungstate of calcium. To Mr. Tesla also the medical profession owes a debt of gratitude for his development of the new art, photographic and fluoroscopic. He reports that he has clearly seen the interior organs of the human body, and even detected the rays after their passage through three men standing near together.

The world cannot be too grateful to men like Edison and Tesla, who unselfishly devote their entire individual energies and the great resources of their laboratories and of their experience to the solution of scientific problems like the "X" ray and its practical applications. [At this point a large portion of the audience filed by the fluoroscopic screen and viewed the bones of their hands in the fluoroscope. Also the lights in the hall were turned out and the bones of the forearm and other objects were exhibited to the entire audience upon a large fluoroscopic screen.]

(b) **Photography.**—[Here followed an exhibition of taking an "X" ray picture. The patient, brought by Dr. Saxl, was believed to have a piece of a needle in her hand. An eight minutes' exposure produced the accompanying picture, which was immediately developed and the negative passed about the audience.¹]

III. [The speaker showed various lantern slides, explained their working, and then continued:]

We are now in a position to draw some deductions as to the applications of the "X" ray in medicine and surgery.

Bones and Osseous Formations.—

The most obvious application of the "X" ray is to present to the eye a picture of the bones of the body, individually and in their relations to each other and to other tissues. By this means it is possible to detect and to diagnosticate irregularities, deformities, malformations, congenital or otherwise, of bones, and likewise to detect the existence of fractures and dislocations, the coexistence of both or the existence of one to the exclusion of the other. Diseases of the bones which vary their density, either by increasing or diminishing it, like exostoses, tuberculosis, and sarcoma, are clearly located. The various stages of the union of fractures are outlined. One of the radiographs I have presented depicts the slight malposition and a change in the marrow cavity at the ends of the fractured extremities in a case of an ununited fracture of the radius. Another locates what is presumed to be tuberculous disease, and is certainly some form of disease of bones of the wrist, in a case which has thus far for five years defied diagnosis and treatment. An operation, soon to be made, and not justifiable for mere ordinary exploration, will soon decide upon the nature of this disease.

The further possibilities of bone pictures alone are very great. By their aid the obstetrician may determine the position of the fœtus in its latest stages

of development within the uterus. Already I have taken one radiograph which plainly shows the child's head and the mother's vertebræ. I only await a favorable opportunity to repeat this with a result which will be satisfactory to any observer. Even now the fœtus may be plainly seen by aid of the fluoroscope and it requires no prophetic vision to state that the time is not far distant when the child may be as easily viewed within the womb as the coins within a purse, even to the extent of its sex.

Another promising field of research is the detection of calcareous infiltrations involving, for instance, the arteries, or occurring in the lungs and other tissues. Calculi in the kidneys, in the bladder, in the salivary ducts have already been successfully located.

The stages of ossification and the epiphyseal relations of the osseous structure in children may be pictured, as is demonstrated in the picture of the entire skeleton of an infant five months of age, shown here to-night. The radiograph here exhibited shows plainly that it will be possible to detect spinal disease either in children or in adults.

In Dentistry.—Already I have had the pleasure of demonstrating before the Odontological Society that the "X" ray locates the hidden fangs of teeth, the presence of foreign bodies about the roots, the existence and extent of unsuspected fillings, the size of the pulp chamber of the tooth, the presence of teeth not yet erupted, and the existence of localities of disease at the roots.

Comparative Anatomy.—Akin to the interest to the surgeon

and to the dentist as relates to osseous tissue is the interest to the comparative anatomist of an opportunity to study the bony structure of animals, the higher as well as the lower. The radiograph of the fish shown to-night is most accurate and fascinating in its almost lacework outline of bony structure.

Foreign Bodies.—The detection of foreign bodies, particularly those of a metallic nature, is already an established fact. Bullets and shot are often embedded in bone or situated close to it, but the "X" ray detects them. The same is true of needles and other pieces

¹ Photographic prints of all my negatives, now a fairly large collection, may be obtained of Mr. E. B. Meyrowitz, 104 East Twenty-Third Street. A descriptive catalogue will be furnished upon application to him.

of steel. Glass, though partially permeable by the ray, affords a reliable picture of its location.

Germicidal.—I am inclined to dismiss this much vaunted claim made for the "X" ray with the remark that if two animal organisms exist side by side, one a bacterium, the other an animal cell, then what affects one affects the other; the "X" ray, if germicidal, is also homicidal.

Soft Tissues.—One of the most unexpected and as yet a most undeveloped, but obviously one of the most useful, applications of the "X" ray, is to locate the position of soft tissues, and not alone to indicate that they are the subject of disease but to locate even the area over which the disease extends.

In the radiograph of the infant the liver is plainly shown in outline, the heart is shown and mapped out in relation to the usual landmarks. Organs distended with gas, such as the stomach and intestines, allow the "X" ray to pass freely, and thus the record of their location and size is made.

These findings in relation to the soft tissues upon a radiograph are but the beginnings of a new art of diagnosis. In delineating and demarcating the organs and tissues, we shall soon arrive at refinements of method and of technique in relation to time of exposure, posturing, etc., which resemble the skill of the practised photographer, for an exposure may be so timed as to depict clearly the soft tissues and their interrelations. An overexposure, for instance, effaces every record upon the plate except that of the bones and may even easily efface that, while an underexposure gives a negative which is full of delicate ghost-like and yet clearly defined outlines of skin, muscle, tendon, veins, and arteries. Negatives of the latter type are far stranger and more startling to the investigator than the mere crude outlines of bones. The mind walks in among the tissues themselves. It is their ghost or their astral form that stands depicted.

But stranger still are the revelations of looking through the living fleshly body by aid of the fluoroscope. First are seen the vertebrae, the greater bones, the ribs, and then to the astonished gaze, in dark outline but moving, may be seen the beating of the heart, the rise and fall of the ribs in respiration, and the movements and rhythmical displacement of organs. I have seen these organs plainly outlined and noted changes in their density due to disease.

We need not become imaginative or speculative in a presentation of this subject, particularly as it is not yet possible to demonstrate to a large audience all that the experimenter himself has seen in the stillness and favorable circumstances of his own laboratory.

But, gentlemen, in conclusion it may be said, that if the practical development of this new art of what may be called inside-seeing or esography progresses yet another month at the rate it is now progressing, you will see with your own eyes and easily, not alone the skeleton construction of your neighbor or your patient, but also the location of his organs, the shape of his muscles and tendons and veins and arteries, nay, more, the variations in density of structure of these parts, and therefore the seat and area of their diseases.

"Many things that are hidden shall now be revealed."

Castration and Urination.—Power to void the urine naturally is usually one of the first results of castration. It is not always permanent. Atrophic changes in the gland begin after a few days. The explanation, therefore, is that ligation of the spermatic plexus produces active stimulation, tonic spasm of the muscles, etc.—MOULLIN.

WANDERING PHLEBITIS (PERIPHLEBITIC LYMPHANGITIS).¹

By WILLIAM P. NORTHRUP, M.D.,

NEW YORK.

THE purpose of this paper is to raise the question whether much of the so-called phlebitis complicating typhoid fever, influenza, and other infectious diseases, may not be in reality periphlebitic lymphangitis. The following illustrative case is submitted in favor of the view that it may be:

The patient was a woman seventy-two years old, well preserved, cheerful, energetic—one of whom it was said she was always "happy and interested in everything about her."

Her father and brother had frequent hemorrhages from the nose, which seem to have been moderate; another brother and a sister died of hemorrhage of the lungs; the patient herself had from childhood been subject to frequent profuse nose bleedings and hemorrhage from piles. She had several miscarriages before the birth of her one living child, after which birth she suffered from milk leg. Apart from the above, there was no significant family or personal history; no gout, no rheumatism. The patient herself had never suffered any serious illness.

One personal peculiarity of the patient was the conspicuousness of her veins in all parts of the body. From early adult life she had been unable to wear a low-necked dress because of this, and at the time of her illness, at the age of seventy-two, the veins were showing in her delicate skin in a manner most rare; the dark purplish color in contrast with the fair skin made one think of veins painted on a manikin by a rather clumsy amateur. This peculiarity is mentioned not because it suggests anything in the etiological line, but because it by chance afforded an excellent opportunity for observing any changes in superficial veins.

The history of the illness now described began with ill-defined feelings of not being in usual good health for one to two weeks, during the last two days of which time she experienced pain in the region of her left hip. It was afterward recalled that the patient, contrary to her habit or temperament, was very much depressed in spirits. To improve her general condition her daughter took her to drive and sought to entertain her by a visit to a loan art exhibition. While there the patient, to use her daughter's words, "seemed to give out altogether," and wished to go away. Thinking a little drive would do the patient good, they turned into the park. Presently the patient became "dazed," stupid, could not see, talked incoherently, became ghastly pale, could not answer questions, and appeared to be dying. The daughter hurried the patient home and to bed. When undressing her it was observed that the whole left leg was swollen and the left thigh looked bruised. Very soon after this I examined the patient, finding the left limb considerably swollen, normal in color, warm, and pitting a little on pressure, with something to attract attention in the left groin. There was diffuse boggiess over the whole region. On pressure in Scarpa's space, an irregular, slightly nodular induration and moderate deep tenderness was observed. The tenderness was not so severe as to preclude a thorough examination, but the boggiess rendered it difficult to determine definitely the condition of the underlying parts. The point which gave rise to the most anxiety of all in the examination was the fact that no pulsation could be felt in the femoral artery. On the other side it could be distinctly and easily felt, and subsequent examinations proved that there was no abnormality in the collocation of parts on the affected side.

¹ Read by title before the Association of American Physicians, Washington, May 2, 1896.

The case stood for the time, then, as follows: Sudden prostration; absence of femoral pulsation in left Scarpa's space, swollen limb; color of limb normal; temperature not sensibly different from that of its fellow. Body temperature, 103° F.; stupor, alternating with moderate delirium.

At this point in the history Dr. H. F. Walker saw the patient in consultation. His diagnosis was "lymphadenitis" and consequent diffuse œdema. The swelling in a confined space and œdema about it, caused the artery pulsations to become imperceptible. This diagnosis seemed at that moment to explain all the symptoms. Dr. Walker had seen similar cases.

On the following day about six inches of the internal saphenous vein became hard, with a whipcord feel, and very sensitive, finger-wide redness gradually developing along its course and later a wide irregular œdema, the whole linear area being exquisitely sensitive. After lasting four days the œdema began to subside, then the redness. The vein could easily be seen and appeared to the sight to be normal. The whipcord feel, however, still remained and the parts continued too sensitive to be handled. At this point it was noted that the œdema of the leg had not increased—had perhaps grown less. The patient gradually became more comfortable, the fever subsided, and general improvement was marked.

About a week from the first observation and when the whipcord feel was the only remaining evidence of inflammation about the saphenous, the outer aspect of the thigh in the upper half became tender and diffusely red with a wide area, having a brawny feel. It became apparent that this advance had taken in a loop of communicating veins which were whipcord-like and in a condition similar to that of the internal saphenous. The invasion of this new and extensive region was attended with constitutional symptoms, chilliness, elevation of temperature (101° F.), rapid pulse (125), pallor, sighing, restlessness, marked irritability, and depression of spirits, with petulance and weeping, stupor, and mild delirium. The constitutional disturbance lasted one or two days; the redness began to disappear on the fourth day, œdema was gone at the end of eight days, the whipcord feel and tenderness alone remaining.

At this time it was interesting to speculate whether the lesion was in the vein wall, a thrombo-phlebitis; if it should prove to be such, being a plainly visible vein, it would be interesting to observe what further use the patient would have of the affected veins, aggregating now about eighteen inches in length. After a few days of rest there was another event of interest—another pain, chill (chilly sensations), moderate rise of temperature, whipcord condition of another six inches of vein, finger-wide redness, bordering œdema, exquisite sensitiveness, this time reappearing about the internal saphenous vein, continuous with that of the first attacked. Now it was observed that all signs about the early affected veins had disappeared; there was, furthermore, an indication that the lesion was not of the intima with thrombosis, but that the lesion was extra-venous.

The walls of the veins were apparently entirely normal: blood could be easily stripped out of them, the current creeping back in plain view.

In this manner the process continued. After intervals of repose of from three to seven days, the affection at each recurrence measuring off six-inch lengths upon the vein, there were the same characteristic manifestations of chill, febrile reaction, whipcord feel, finger-wide redness, œdema, sensitiveness, subsidence of all symptoms, and then a complete return of the vein to normal condition.

The process followed the line of the internal saphenous vein to the lower third of the leg and there ceased.

Hope was entertained in the household that "it would pass off at the toes," as suggested by the patient.

After the lapse of from ten days to two weeks another chill with febrile reaction visited the patient, no visible vein being affected; then after another few days a second febrile reaction, similar to the four or five previously experienced, and still no visible vein was affected. While we were speculating as to where the inflammation would next appear, there came a third similar attack, and the internal saphenous in the opposite groin became a whipcord with accompanying œdema. From this point the process intermittently measured off its lengths up the superficial epigastric vein to the breast and there ceased. Still another rest, chill, and fever, and the same process entered upon its march along the course of the internal saphenous. It hitched along one six-inch length downward, halted, made a detour along the loop of external saphenous veins on the external aspect of the thigh exactly as it did on the other side; ceased in this region, in exactly the same way; measured off more and more lengths down the internal saphenous to the lower third of the leg, and ceased at the same level that it did on the first. When the inflammation made its appearance in the second leg all the lesion about the veins of the first affected leg had disappeared; the perivascular tissues of the superior epigastric and the upper portion of the internal saphenous had become quite normal.

When the process ceased at the right ankle and the lesion had disappeared, the patient was well. She has since been well, a period of more than two years.

Whether perivascular lymphatics of the superior epigastric vein of the left side were inflamed before the patient came under observation can be only conjectured. There are reasons for thinking they had been, for the patient had complained of pain in the left hip and had been ill some days before she collapsed in the art gallery. If, then, the inflammation behaved symmetrically in this respect as in all others, about two yards of superficial vein were involved first and last. The only hidden lymphatics affected, so far as known, were those of the pelvis, along which the process advanced from the left side to the right in the interval of its ceasing at the left ankle and appearing at the right groin. As will be remembered, this progression was marked by two chills and two febrile reactions of the same degree of severity and of the same general character as those in the other steps of progression.

The treatment of the case consisted in rest in bed, elevation of the swollen limb (the second affected did not swell), fluid diet, general regulation of the functions of stomach and bowels. Local applications of various kinds were tried. Cotton pads were employed for protection; hot and cold, wet and dry applications, with and without pressure, for relief of pain and tenderness, but no specific treatment was attempted. No alkaline treatment was directed toward dissolving any intravenous clot, neither was any scarification attempted to limit the advance of the lymph-channel infection. Bichloride wet applications were attempted, but caused irritation and were not continued systematically.

Quiet, rest in bed, fluid food, relief of symptoms, general good hygiene was the only aim in the later stages. None of the various plans of treatment tried at the outset seemed to modify the course, and the patient begged only to be left undisturbed.

It seems to the writer that periphlebitic lymphangitis is the correct name for the lesion in the present case. In the writer's experience the behavior of the tissues about superficial veins in typhoid fever has been practically the same. There has been the same whipcord feel, tenderness, œdema, and final subsidence of all evidences of previous inflammation. Furthermore, this inflamed tissue is located quite

often upon limited lengths of vein, in continuity, spreading a little or not at all and disappearing, having apparently let loose no accidental emboli and having left no thrombosis. The masterful way in which so-called thrombo-phlebitis has been cured and veins restored thrombus-free, suggests that the veins in such cases may have had a perivascular inflammation. A coat-sleeved infiltration, the perivascular spaces being crowded with lymphocytes, could easily give the cord-like feel, while yet the intimal coat and calibre remained practically undisturbed.

The writer cannot, at this point, refrain from expressing his opinion that infectious thrombo-phlebitis rarely, if ever, disappears completely, leaving a previous vein. Upon this point discussion is invited.

As to etiology of this variety of lymphangitis the explanation must await the results of animal experimentation or of chance antopsies. Bleeding piles, in the present case, would suggest themselves as a portal for entering infection. The infective process having appeared in the groin, its subsequent migration was along continuous ways, limiting itself to similar tissues. Why it confined itself for the most part to the lymphatics about the superficial veins, apparently selecting those of the internal saphenous and refusing those of the femoral, selecting those of the superficial epigastric and refusing those of the deep, is not easily explained. I have it on the authority of Prof. Geo. Huntington that the superficial veins are better supplied with surrounding lymphatics than the deep. Erysipelas has analogous characteristics and very similar features of appearance and behavior, *i.e.*, in cutaneous and subcutaneous tissues and surfaces.

Briefly to summarize: An aged patient, without previous illness, suffered a migrating lymphangitis which followed for the most part the course of superficial veins. There was no evidence that there was in any part a thrombosis, and the vein was ultimately left in an apparently normal condition.

Its infectious origin, intermitting advances, topographical limitations, suggest a process analogous to that of erysipelas.

Again, the question arises just here as to the possibility and probability of an infectious venous thrombosis ever clearing up, leaving the vein quite normal.

The reason for calling attention to this case is the fact that the migration was so extensive, and, further, that it seems to the writer that this lesion has been often set down by clinicians as phlebitis. Anatomists maintain that the perivascular lymph spaces are not an essential part of the vein wall. There may be no objection to the term "periphlebitis," but periphlebitic lymphangitis would seem to describe the lesion more completely.

57 EAST SEVENTY-NINTH STREET.

Abnormal Labor Pains.—Dr. Schaeffer, of Heidelberg, makes a division in labor pains, those that are purely atonic and those which are partially spasmodic. The most frequent cause of the partially tetanic pains is endometritis of the cervix, which results in a slowed first stage and consequently increased suffering; another cause is the frequent examinations made and irritation which they produce; abnormal position of the uterus may also produce them. In this condition it is not necessary to rupture the membranes, for they usually rupture without special delay. Treatment consists in placing the patient in favorable posture, use of warm baths, and hot vaginal douches. For weak pains, when simple atony of the uterus is present, small hypodermic injections of ergotin are found useful, producing an effect in about eight minutes after administration.—*Centralblatt für Gynäkologie*, No. 4, 1896.

IMPROVED TRACHELORRHAPHY.

By AUGUSTIN H. GOELET, M.D.,

PROFESSOR OF GYNECOLOGY IN THE NEW YORK SCHOOL OF CLINICAL MEDICINE, ETC.

THE benefit afforded by properly performed trachelorrhaphy in appropriate cases is very generally admitted, and though the operation may be applied unnecessarily by some and may be performed incorrectly by others, upon the whole it has perhaps been productive of more good than any other operation in gynecological surgery. The difficulty in those cases which do not yield satisfactory results lies usually in not removing a sufficient amount of the diseased tissue of the cervix, or in removing too much on the outer or vaginal margin and not enough on the inner margin or that next the canal, thus leaving a wedge of tissue which prevents proper coaptation of the flaps and puts too much strain on the sutures. This is partly because the denudation is done with scissors, which can seldom be made to cut through such dense tissue where it is desired to cut. They invariably slip, and considerable trimming is necessary afterward to get the flaps in proper condition for the application of the sutures. This consumes a great deal of time and is a serious disadvantage, as well as the fact that the scissors will frequently cut where it is not desired to cut and too much tissue is removed.

Another serious objection to the ordinary trachelorrhaphy is the great difficulty of inserting the sutures, because of the density of the tissue and the awkward position for the operator of the parts to be united. I venture to assert that any operator would infinitely prefer to do an abdominal section than one of these tedious and fatiguing cervix operations. It is, therefore, because I believe I have simplified the operation and made it quicker and easier, that I have been encouraged to describe the method that I have employed with so much satisfaction.

In the first place, the denudation is done with a knife especially designed for the purpose, which consists of a short two-edged blade set at an obtuse angle to the shaft and handle (see Fig. 1). I am well aware that several knives have been designed and used for this purpose before, but, so far as I know, none have been made upon the principle of this one, and they have not proven satisfactory, else they would be more used. These knives are made in two sizes and lengths, so as to be useful in all cases, since the cervix in some instances is thick and the flaps deep, and in others thin by comparison. The method of using the knife is to seize one angle of the laceration with a tenaculum, transfix it with the knife, which is then drawn forward, making a clean cut and denuding the flap out to the lower margin of the cervix with one stroke. It is then inserted again on the other side and the opposite flap denuded in the same manner. If now the tissue which is to be removed remains attached at the angle, a reverse movement of the knife severs it with its other cutting-edge. Besides the greater ease of denuding with the knife, there is another advantage, *viz.*, it can be inserted and held in such manner as to avoid leaving a wedge of tissue on the inner edge of the wound.

In the next place, a special needle is employed for inserting the sutures. I have abandoned the straight needles and the straight needles with slight bend near the point, and use a nearly half-curved, round needle, much smaller in diameter than the needles usually employed in this operation, with a flattened spear point. These needles can be inserted into the hardest cervix with the greatest ease. I have never yet broken one of these needles, and find that they can be inserted with very much less force than any other needle which I have used.

Next I use for suture material silkworm gut which has been especially prepared so as to render it pliable and easily tied. I do not think catgut, silk, or any suture which is not impervious should be used in plastic work upon the cervix. The silkworm gut is prepared in this manner: Each strand is carefully wiped off with gauze or cotton saturated with ether, and a number of strands are put into a glass tube of suitable length, the ends being stoppered with rubber corks. The tube is filled with a two-per-cent. solu-

FIG. 1.

tion of lysol, one end is left uncorked, and it is placed in a sterilizer in which the solution in the tube can boil for half an hour. The lysol solution makes the silkworm gut very pliable, so it can be tied as easily as catgut, and in addition it renders it thoroughly aseptic.

The operation is further facilitated by placing the patient in the lithotomy position.

Technique of the Operation.—It is of the greatest importance that the patient be carefully prepared for the operation. For two weeks, every second day a

FIG. 2.

tampon of prepared wool soaked in glycerin is placed against the cervix to deplete and soften it. This is removed after twenty-four hours and a copious douche of hot water is projected against the cervix and vaginal vault by means of a syringe giving an interrupted flow. At each sitting for the introduction of the glycerin tampon any cysts of the Nabothian glands detected on the cervix are punctured and emptied.

Two days previous to the operation the patient is given a calomel-and-soda purge and she is placed

upon a restricted diet. The morning of the operation she is given a saline cathartic, the vulva is shaved and washed in a one-per-cent. solution of lysol, and she is given a vaginal douche of lysol solution also.

When anesthetized, she is placed upon the operating-table in the lithotomy position, a speculum is inserted, and the vagina is thoroughly scrubbed with a one-per-cent. solution of lysol and afterward irrigated with a solution of bichloride, 1 to 2,000. A ligature is then passed through each lip of the cervix and tied with a long loop, which is held by an assistant, usually the nurse, who also holds the speculum and who stands at the left of the operator. The cervix at the angle on one side (the left first) is seized with a tenaculum and the knife (as shown in Fig. 1) is made to transfix the cervix on one side of the angle. This done, the tenaculum is loosened and reinserted in the lip near the lower border near where the line of denudation is

FIG. 3.

to terminate on that side (see Fig. 2), and the knife is drawn forward, making the denudation with one stroke. The knife is again inserted at the angle on the same side of the cervix, but on the opposite flap, and it is denuded in the same manner. If the tissue to be removed remains attached at the angle, a few strokes upward with the other cutting edge of the knife severs it so it can be removed. The same thing is repeated on the other side (see Fig. 3).

In making the denudation the knife is held at such an angle that rather more tissue is taken from the inner than from the outer surface, so as to remove the

FIG. 4.

ridge along the margin of the new canal of the cervix, which if left would prevent satisfactory coaptation of the flaps. In denuding with scissors this nearly always remains and must be carefully trimmed off afterward, considerable time being consumed in doing so.

The sutures of silkworm gut are inserted by means

of the special curved needles described above, being threaded with a carrying-thread (see Fig. 4). It is preferable to insert the outer or lower suture first, so as to get perfect coaptation of the edges of the flaps where the new external os is to be formed. It will not be difficult to insert the other sutures if the loop of this first one is left long, so as not to draw the flaps together. The sutures are, of course, inserted on the vaginal margin of the flap and brought out on the margin of the new canal upon the mucous surface and not upon the denuded surface. As each suture is passed it is clamped by pressure forceps and handed to an assistant to hold. All the sutures on both sides (three on each side being usually sufficient) are inserted before any are tied. Then the flaps are separated, and they are thoroughly irrigated with a solution of bichloride, 1 to 2,000. The sutures are tied from without inward, or from below upward, tying that at the angle last. The ends are cut about half an inch from the knot, the vagina is washed out, and the patient is removed from the operating-table to the bed. No dressing is applied to the cervix or vagina.

351 WEST FIFTY-SEVENTH STREET.

plete relaxation, extension was made from in front with counterextension at the shoulders, the greatest care being taken that no sudden movement should be made. There was an immediate and gratifying response to these efforts, respiration was not at all affected, and we could then distinctly feel the spinous process of the fourth cervical vertebra in line with those below, while there was complete disappearance of the deformity. Having thus reduced the dislocation, the next problem was to retain the bones in their proper position. The solution decided upon was a plaster-of-Paris cast, which was applied so as to extend from the occiput and the thyroid cartilage above to the first dorsal vertebra and the sternum below, care being taken to allow sufficient room for the neck. The patient was then placed in bed and watched carefully for three hours, during which time his condition remained satisfactory. He was allowed to go about in a week, the plaster was removed in three weeks, its place being taken by roller bandages, and he was discharged cured in five weeks from the date of the injury. Since then he has been attending to his work as a compositor, and he is apparently none the worse for the accident.

DISLOCATION OF THE FOURTH CERVICAL VERTEBRA—REDUCTION—RECOVERY.

By WILLIAM H. NAMMACK, M.D.,
NEW YORK.

GEORGE W—, aged twenty-one, on September 2, 1895, while bathing at Far Rockaway, L. I., dived into shallow water and struck his head against the bottom. The forcible flexion of his head resulted in a dislocation. He became unconscious and remained so for about an hour as a result of the concussion of the brain, but this condition responded readily to the usual remedies.

On examination by Dr. Thomas J. Kearney and myself a marked deformity was apparent. We felt the vertebra prominens, and the sixth and the fifth vertebrae were also found in their normal position. Above these, however, the spine was bent forward, and a wide gap posteriorly was easily felt and was even visible. The head was completely immobile and the malposition of the parts was peculiarly characteristic. There was no paralysis either of motion or of sensation, severe pain, of which the patient complained, being the only pressure symptom. Deglutition of liquids was difficult and painful, that of solids impossible.

By placing the finger in the posterior part of the mouth, the projection forward of the displaced vertebra was easily felt, so that we believed that the articulation between the two vertebrae, the fifth and the fourth, was torn open, that the supraspinous and the infraspinoous ligaments, the ligamentum subflava, and posterior common ligament were torn through, while the ligamentum nuchæ remained intact, drawing the occiput downward toward the vertebra prominens and so increasing the deformity.

Upon consultation it was decided to endeavor to reduce the dislocation, and the dangers incident to such a step were explained to the family, who left the treatment entirely to our discretion. Drs. Burns and Bumster, whom I called upon for assistance, acquiesced in the following plan of treatment:

The patient was placed prone upon the table with his head and neck extending beyond its end, and supported in that position during the administration of ether. As soon as the anæsthetic had produced com-

HYDATIDIFORM MOLE.

By WILLARD GILLETTE, M.D.,

ROSEBOON, N. Y.

A MARRIED lady, eighteen years of age, and the mother of a child twenty-two months old, was regular in her menstrual periods until September 1st last and noticed nothing again until October 25th, when she began to have uterine hemorrhage, at times profuse. November 7th I was consulted in regard to this flow and, regarding it as simple menorrhagia, gave her a three-grain pill of ergotin three times daily, to check hemorrhage, which it did to some extent. This treatment was continued until November 24th, when I saw the patient for the second time and made an examination of the abdomen. I found the uterus about the size of a child's head and tense and I diagnosed the case as one of pregnancy. This the patient strongly denied and said she had never noticed any enlargement until then. November 28th, about eleven o'clock at night, I was called to see her and found her in considerable pain and having some hemorrhage; I gave her an anodyne. I made a vaginal examination and found the uterus reaching to the umbilicus. I was very much surprised to find this rapid increase in size in this short time, for, as before stated, the uterus was just above the pelvis and about the size of a child's head on November 24th, only four days before, but now it reached the umbilicus. I found the uterus very low and distended, of a doughy feeling, and the os so far displaced toward the sacrum that I could scarcely reach it and also slightly dilated.

To say that I was astonished at this state of things is putting it mildly. However, I decided to await developments. In the morning I found the patient in a chair, with no pain and no hemorrhage. About noon I saw her again when she was having some hemorrhage. Vaginal examination revealed the os more dilated. I used a tampon and gave one drachm of ergot, fluid extract, followed once in two hours by a three-grain pill of ergotin. The pain continued.

About 5 P.M. expulsive pains began and after a little time the patient said the child was born. Upon examination I found a mass of hydatids or hydatid cysts resembling white currants, and then for the first time in the history of the case did I find that I had to deal with "a molar pregnancy," the first one in my experience. These cysts continued to be expelled

until between three and four quarts were taken, and among them a fœtus of perhaps two months. The hemorrhage ceased immediately. I gave ergotin pills at four-hour intervals during the night. I saw the patient December 2, 1895, and found her doing nicely.

Progress of Medical Science.

A New Form of Incontinence of Urine.—Dr. Abarran calls attention to a new form of incontinence of urine in young girls, which is due to a defect in the development of the internal genital organs (*New York Medical Journal*). He relates the case of a patient who had been troubled with incontinence for six years. It had appeared when menstruation was established, and all treatment had failed to bring about a cure. The patient was thin, badly-developed, and nervous. The external genital organs were normal, but an examination revealed the absence of the anterior cul-de-sac of the vagina; the vaginal wall was tense, and it was inserted directly on the anterior lip of the cervix uteri; the posterior cul-de-sac was well developed; the uterus was small and conoid; the left ovary was in its proper place, but the right ovary was nearer than normal to the anterior vaginal wall. The bladder and the urethra were normal, but a malformation of the internal genital organs existed, which consisted of an abnormal adhesion of the posterior wall of the bladder to the anterior surface of the uterus. This explained the cause of the incontinence. When the patient lay down the uterus became displaced backward and dragged with it the posterior wall of the bladder, which adhered to its anterior surface; when the patient stood up the uterus became displaced forward and pressed heavily on the posterior wall of the bladder, thus causing the vesico-urethral sphincter to remain open. An incision was made in the anterior wall of the vagina, extending from the neck of the uterus almost to the urethra. The uterus was detached from the bladder, and the inter-utero-vesical space was packed with iodoform gauze. At the end of fifteen days the faradic current was applied to the neck of the uterus three times. This treatment, says the author, resulted in a complete cure.

Trional in Epilepsy.—Dr. H. P. Boyer reports his observations in regard to the clinical use of this drug by Dr. S. Weir Mitchell, as the results obtained from this treatment were such, he says, that it was thought advisable to publish them. In most instances where trional was used the patients were in some way benefited (*New York Medical Journal*). Either the number of attacks was diminished, their severity lessened, or the general physical condition of the patient improved. Early in 1894, says Dr. Boyer, Dr. Mitchell, pleased with the results of this treatment in his private practice, began to use it in his out-patient service. The results of its use and the drawbacks are stated in an account of thirteen cases. Others, says Dr. Boyer, might be added to the list, but the patients neglected to report at the hospital, and the results could not be carefully watched. Others, again, suffered so much from drowsiness and vertigo, and derived so little benefit in regard to the diminution of the number of attacks, that the treatment was not kept up for more than two or three weeks. Of the thirteen cases referred to, in ten there was a marked decrease in the number of attacks during the treatment, and the physical symptoms also were singularly improved. In five of the cases the number of attacks was less under the trional treatment than under the bromide treatment: in two others, however, the bromides gave more satisfactory results. Dr. Mitchell believes, says Dr.

Boyer, that trional may often prove an efficient substitute for the bromides, and he states that he has seen no ill effects follow its continuous use for many weeks. It is well, he says, at times to give the bromides in the daytime and trional at night.

Gunshot Wounds of the Abdominal Viscera.—Dr. Randolph Winslow (*Bulletin of the Maryland University Hospital*, vol. i., No. 1) summarizes his views as follows: 1. In view of the almost uniformly fatal result of gunshot wounds of the abdominal viscera, when treated conservatively—that is with opium, rest, and starvation—it is the bounden duty of surgeons to subject such cases to laparotomy, and to repair, so far as possible, such injuries as may have been inflicted. 2. Operate at once, and do not wait for symptoms of perforation of the intestines to occur—that is, for the development of peritonitis—or the golden opportunity will be lost and the operation will be too late. 3. The condition of shock in abdominal injuries usually means hemorrhage, and it is best not to wait for reaction; otherwise the only possible chance of saving life may be lost. 4. The exploration of the abdomen should be thorough, and for this purpose a very free incision may be necessary. 5. All bleeding vessels must be secured, and all intestinal wounds must be sutured. 6. It is generally best to open the abdomen in the linea alba, but in some cases it may be preferable to operate at the site of the wound. 7. Operate as speedily as possible, but do not hurry.

Indications for the Induction of Abortion.—Dr. Jeffé (*Medizinische Neuigkeiten*, No. 45, 1894) after a study of the literature of the last ten years fixes the indication for inducing abortion as follows: Absolute indications—1. Uncontrollable vomiting of pregnancy. 2. Incarceration of the gravid uterus. 3. Obstruction of the pelvic outlet by tumors or exudates. 4. Progressive and pernicious anæmia. 5. Grave chorea. Relative indications—1. Great contraction of the pelvis with the conjugata vera below five centimetres. 2. Pulmonary emphysema with signs of degeneration of the heart. 3. Nephritis, especially with eclampsia. 4. Chronic heart disease. 5. Other general diseases of the mother which would jeopardize her life at that time of delivery. The author holds that a conjugate vera of six centimetres and advanced pulmonary tuberculosis should not be regarded as indications for abortion, as it is not just to sacrifice a future life for one that is "certainly lost."

Syphilis and the Etiology of Atheroma.—Dr. Weber (*American Journal of the Medical Sciences*, May, 1896) concludes: 1. That atheroma of the aorta, though often preceded or accompanied by inflammation, is itself a merely degenerative process; that syphilitic or other inflammation may locally predispose to atheroma. 2. That aneurism of the aorta is induced more often by the yielding of a portion of its wall affected by syphilitic or other inflammation than of a portion affected by simple atheroma.

Dislocations of the Hip.—In a monograph on this subject, to which was awarded the Samuel D. Gross prize for 1896, Dr. Oscar H. Allis discussed the following points: 1. The capsule is the most important agent against traumatic dislocations of the femur. 2. For the laceration of the capsule and dislodgment of the head of the femur the femur is employed as a lever. 3. Every lever has a fulcrum; the fulcra required in dislocations of the femur are bony and ligamentous. 4. Dislocation by thrust, if possible, is infrequent. 5. Reduction by circumduction is the simplest, the most brilliant, and the most hazardous of all modes of replacement. 6. Method suggested for reduction of dislocation of the head of the femur when associated with fracture of the shaft.

MEDICAL RECORD:

New York, July 4, 1896.

THE ANTITOXIN QUESTION.

AT the present time, when the antitoxin treatment for diphtheria is so much under discussion, the report of the American Pediatric Society will be read with much interest. It is only by such thorough work in the collection of statistics from widely different sources, and the fair and careful estimation of all possible controlling influences, that valuable and impartial facts can be obtained. Under such circumstances only can fair opinions be formed and proper conclusions drawn. Too much praise cannot be given to the committee having the matter in charge for the painstaking manner in which the work has been done. Never before has a similar investigation been made in which more vital interests have been at stake and in which it was more necessary that some general principles should be established upon which proper conclusions could be founded. It is fair to say that upon the question whether or not antitoxin is valuable in diphtheria rests the whole theory of the serum treatment of infectious diseases. Too much care cannot be taken in properly sifting all the facts *pro* or *con*, bearing upon the important point at issue. The conviction cannot be resisted that the great preponderance of professional opinion is strongly in favor of the method. This is abundantly proved, thus far at least, by the widespread use of the remedy and the growing conviction that it has a marked and striking effect in reducing mortality. Notwithstanding, however, the large number of statistics already collected, we are not yet prepared for final conclusions. There is no denying the fact that bacteriology pure and simple has appropriated more than its just share of credit in the present aspect of the question, nor is there any doubt of a desire among the very active workers in this now promising field of investigation to still more magnify the importance of their researches at the expense of clinical experience, upon which, after all said and done, the practical use of every therapeutic measure must finally rest. Thus the tendency has very naturally shown itself to found the diagnosis absolutely on the bacteriological examination, with the result of greatly enlarging the number of cases and proportionately reducing the rate of mortality. Not every throat containing the Loeffler bacillus is necessarily a malignant case. In times past there was no way of deciding between a malignant and a benign case save by the different constitutional dis-

turbances that were manifest. In a great many of these cases the local lesions were apparently the same. Bacteriology has made great advances in clearing up many cases of reasonable doubt, but the broad generalizations regarding the true significance of a given microbe are not yet so firmly established as to be beyond the possibility of doubt or above the right of challenge.

The Pediatric Society has shown a very proper spirit in its efforts to eliminate these sources of error, and in this respect more particularly has shown the example for future investigation along very promising lines. The truth will eventually be found in the middle ground between the extreme views. The society has made the most of its opportunities, which have been quite extraordinary, in raising the discussion to such a level, and in this respect has set the pace for all similar inquiries.

The conditions of the inquiry have been fair and reasonable, and need only to be carefully studied to be properly appreciated. It was eminently proper that the test of the remedy should be made on children previously well nourished, such, for instance, as could be seen in private practice; that the number should be widely distributed, and be sufficiently large, including all cases reported, to reduce errors of calculation to a minimum and establish a proper estimation of percentages. A crucial test has been made on the basis of mortality of the severer cases which required intubation. It can be seen that so far the favorable figures are on the side of antitoxin. Still, as before intimated, we are just beginning to study this question from the proper standpoints, and while the great majority of the profession may very properly continue the use of antitoxin, we are very much in need of many more facts before we can silence absolutely such as still need to be convinced of its efficacy. The case is still being very successfully argued on the side of antitoxin, but the great, silent, careful, powerful jury of the profession is not yet ready with its final verdict.

THE TREATMENT OF PRURITUS.

IN a recent issue of the *British Medical Journal*, a discussion on the pathology and treatment of pruritus is published, in which a number of prominent dermatologists took part. The discussion was limited in the main to the consideration of pruritus not associated with any distinct skin eruption, although an able discussion of the relation of this symptom to skin disease is given by Dr. Brooke. It is interesting to read over simply the list of the causes which lead to persistent and obstinate itching of the skin. Pruritus occurs in old people, and seems to be merely one of the symptoms of an involution of the epidermis. It attacks some persons in the winter time, because a lower temperature is enough to bring out the symptoms in those with a predisposition to the trouble. There are curious types of pruritus, which have been called by some "brain itch" and by others "pruritus mentis." In this the itch is a pure hallucination, the locality being not in the skin but in the cortex of the brain. There is a

pruritus that comes on after people take strong tea or strong coffee, and another kind which develops after eating badly cooked oatmeal or indigestible starchy food. General pruritus has been known to be caused by tapeworms, and there is a popular belief that itching of the tip of the nose is a reflex pruritus from pinworms in the rectum. One of the speakers in the discussion stated that he had seen in recent years many cases of pruritus ani from bicycling and polo playing. Pruritus, however, in its commoner manifestations is probably most often seen in connection with a gouty diathesis or with diabetes, in which cases there is often some eczema associated with it.

The foregoing are some of the facts, sufficiently familiar, but presented anew by the speakers in the discussion referred to.

The subject of treatment was touched upon by half a dozen of the gentlemen, most of them referring to measures which they had found useful in some particular form of the trouble. Dr. Garrett Anderson recommends for the pruritus of neurotic women and "men of feminine habits"—whatever she may mean by that—rest before meals, increase of food, silk underclothing, and cod-liver oil. Dr. Myrtle recommended, in vulvar and anal cases, the free use of an ointment composed of fifteen to forty grains of potassa fusa to one ounce of lard. Two physicians, Dr. Waldo and Dr. F. H. Barendt, advised the use of mustard leaves over the spinal cord or of blisters over the same area. Dr. Barendt also recommended strongly, as a local application, hot olive oil containing two per cent. of carbolic acid for five minutes night and morning. We find nothing specially new in the line of drugs for internal use. Dr. Anderson has had the best results from the administration of atropine or of one of the coal-tar derivatives, and by using electricity. Atropine is given subcutaneously, in doses of one-one-hundredth of a grain, gradually increased. Of the coal-tar derivatives, antipyrin is the best, but it is to be given in large doses. Mention is, of course, made of the ordinary precautions as regards diet and bathing, things which all physicians would naturally take into consideration.

AN IMPOSSIBLE WORD.

We have received a reprint of an article entitled "Aeroporotomy," written by a medical practitioner in Cleveland who has a laudable desire to better our medical nomenclature. Our heart sank as we read the title, for the obvious meaning of the word would be cutting up an aeronaut. These poor creatures run enough risks through collapse of their parachutes, and it did seem too bad that any of them should have come under the knife of a Cleveland surgeon. We were somewhat relieved, however, to find that the dreadful word was only one which the author proposed as a general term to express any or all of the various methods for letting air into the air passages. As such, the attempted coinage is not a success. We do not think the need of any such inclusive term is very strongly felt, but if one wants to

say opening into the air passages, he had better stick to the English. It is quite expressive and fairly well understood in this country.

News of the Week.

A Hospital Quarrel in Australia.—The members of the attending staff of the Adelaide Public Hospital, of Adelaide, South Australia, have resigned in a body on account of some disagreement with the authorities, the nature of which is not stated in the dispatches. The government is stubborn, and has sent to England to secure a full staff of physicians and surgeons to serve on a salary. The local profession is unanimous in support of the resigning staff, and those who may take their places on the invitation of the government will not receive a very cordial welcome from their confrères. This will doubtless, however, not interfere with the success of the government's scheme, and indeed one well-known London man, Dr. Leith Napier, has already accepted the invitation, and his example will probably soon be imitated.

Dr. Hans von Hebra, the son of the "Father of Dermatology," formerly privat-docent, has now received the appointment of professor at the University of Vienna.

A New Greek Medical Journal.—We have received the first number of *Ἱατρικὴ Προόδος* (*Medical Progress*), a monthly journal published in Syros, under the editorial management of Dr. John A. Phoustanos. Each number is to consist of twenty-eight quarto pages, with a supplement containing a serial treatise on the "New Remedies" by the editor. The first two numbers contain several interesting articles on various subjects.

Resignation at the Woman's Hospital of Philadelphia.—Dr. Anna M. Fullerton, physician-in-charge of the Woman's Hospital for the past ten years, has resigned her position in that institution. The managers have not yet appointed her successor.

New York Medical Licenses no Longer Accepted in Pennsylvania.—The Pennsylvania State Medical Council has rescinded its rule accepting licenses from the New York State Board of Medical Examiners, in retaliation for the refusal of the New York examiners to accept the licenses issued by the Pennsylvania board.

The University of Utrecht has just celebrated the two hundred and sixtieth anniversary of its foundation on June 22d.

Professor Virchow has had a narrow escape, having been thrown down in the streets of Berlin by a bicycle. Fortunately he suffered no severe injury.

Dr. Joseph McFarland, demonstrator of pathological histology and lecturer on bacteriology in the University of Pennsylvania, has been elected professor of pathology in the Medico-Chirurgical College, in succession to Dr. E. B. Sangree, recently elected to a similar chair in Vanderbilt University.

Medico-Chirurgical College of Philadelphia.—Dr. Isaac Ott, professor of physiology, has been elected dean of the Medico-Chirurgical College, vice Dr. Ernest Laplace, resigned.

College of Physicians of Philadelphia.—At the stated meeting of the College of Physicians of Philadelphia, held on June 3d, Dr. Joseph Leidy read a "Note on Infantile Scurvy," reporting two of nine cases that had come under his observation. Dr. Oscar H. Allis read a paper entitled "The Mechanism of Dislocations of the Shoulder and Hip Deduced from their Accidental Restoration," and presented specimens as follows: (1) Impacted fracture of the neck of the femur; (2) fracture of the neck of the femur, partly intracapsular, partly extracapsular, with transfixion of the capsule, and accompanied with flexion of the femur at the hip. Dr. Robert G. Le Conte reported the case of a man who had received a bullet wound of the neck, in which the missile could not be found upon examination by the ordinary means, but which after some time was located by means of skotography. After extended search the bullet was found in front of one of the lower cervical vertebræ, between which and the œsophagus in front an abscess had formed. This is an instance of the saving of life which is to be credited to the new light. The following were elected to fellowship: Drs. T. C. Ely, H. D. Beyea, A. H. Cleveland, L. S. Smith, J. C. Da Costa, W. M. Angney; and the following to associate fellowship: Sir George Murray Humphrey, Bart., of Cambridge, England; Dr. George M. Sternberg, U. S. A., of Washington, D. C.; Dr. Phineas S. Conner, of Cincinnati, O.; Dr. T. McLane Tiffany, of Baltimore, Md.; and Dr. William T. Lusk, of New York City.

The Lepra Bacillus has been found in the blood, as well as in the tissues, by Dr. Bouffé, of Paris.

Vital Statistics of Philadelphia.—For the week ending June 20th there were reported to the Philadelphia board of health 414 deaths, of which 174 occurred in children under five years of age. Among the most important causes of death were: Pulmonary tuberculosis, 46; cholera infantum, 32; heart disease, 30; pneumonia, 28; marasmus, 26; convulsions, 22. The following figures show the morbidity and mortality of diphtheria, scarlet fever, and typhoid fever for the weeks ending June 13th and 20th respectively:

	—JUNE 13.—		—JUNE 20.—	
	Cases.	Deaths.	Cases.	Deaths.
Diphtheria	46	8	40	11
Scarlet fever.....	16	..	13	1
Typhoid fever	39	9	30	3

State Medical Examinations.—At the Pennsylvania State Medical examinations, held at Harrisburg on June 16th, there were three hundred regular applicants, about seventy homœopathic, and several eclectic. It was discovered that one of the applicants had in advance obtained a copy of the examination questions, and was disposing of his information at the rate of \$25 to all who wished it. The discovery was made in time to change the questions, and the confession of the offender was followed by his

proscription from the practice of medicine in the State of Pennsylvania. The examination of applicants for a license to practise medicine in Delaware was held on June 16th, 17th, and 18th. The examination of graduates in regular medicine was held at Dover; those of graduates of homœopathic schools at Wilmington.

Philadelphia County Medical Society.—At the stated meeting of the Philadelphia County Medical Society, held on June 10th, Dr. B. Meade Bolton, director of the bacteriological division of the board of health, read a paper entitled "The Examination of Cultures from Cases of Suspected Diphtheria." The data were abstracted from the first annual report of the bacteriological laboratory of the bureau of health, and were summarized in the MEDICAL RECORD of March 7th, p. 347. Dr. Edward Jackson read a communication entitled "The Profession, the Opticians, and the Public," in which he made a strong plea for greater care and attention on the part of ophthalmologists in the correction of refractive errors of the eye. He condemned the practice, now happily declining, of prescribers of glasses accepting commissions or other form of compensation from oculists. Dr. Ernest Laplace read a paper on "The Surgical Treatment of Insanity," reporting several cases presenting symptoms of mental aberration, in which relief was afforded by trephining, separation of dural adhesions, removal of old blood clots, etc. Dr. J. P. Crozer Griffith reported "A Case of Varicella Gangranosa," in which, following an attack of croupous pneumonia, diphtheria, rubeola, and varicella occurred synchronously in a child twenty-two months old. Large bullæ formed in various parts of the body, the breaking down of whose walls and the evacuation of their contents were followed by ulceration and gangrene. Upon post-mortem examination the trachea was found occluded by diphtheritic membrane, although the larynx was free.

"A Medical Jack the Ripper" is what the gentlemanly premier of South Australia called the former head of the gynecological staff of the Adelaide Hospital, who had resigned with his colleagues rather than submit to be ruled by a board, one of whose members was a practitioner who had been expelled from the local branch of the British Medical Association.

Obituary Notes.—DR. GEORGE C. SHATTUCK CHOATE, of Pleasantville, Westchester County, died suddenly in this city on June 28th. He was born in Salem, Mass., in 1826. He was the oldest son of Dr. George Choate, of Salem, and a brother of Joseph H. Choate and William G. Choate, of this city. Dr. Choate was graduated from Harvard College in 1846 and from the Harvard Medical School in 1849. He was for ten years superintendent of the Massachusetts State Asylum for the Insane at Taunton. Thirty-six years ago he established a sanatorium near Pleasantville, and it was there that Horace Greeley died on November 29, 1872.—DR. JOSEPH BAUER, of St. Louis,

a son of Dr. Louis Bauer, died on May 22d of Bright's disease, at the age of forty-two years. He was a native of Brooklyn, N. Y., and was graduated in medicine from the Missouri Medical College.—DR. C. H. BAHL, a graduate of the University of Pennsylvania in 1864, died in Philadelphia on June 14th.

Measles in Costa Rica.—The *American Practitioner and News* says that a fearful epidemic of measles and mumps is reported by private letters to be raging in Costa Rica. More than ten thousand children are estimated to have died from these maladies during a period of three weeks. All official reports are rigorously suppressed for commercial reasons.

Li Hung Chang's Bullet Found by the Roentgen Rays.—During the stay of Li Hung Chang in Berlin he visited the Charlottenburg Polytechnic and submitted himself to a Roentgen-ray examination, which revealed the location of the bullet fired by the would-be assassin of the Chinese statesman at Shimonoseki, Japan, when the treaty between China and Japan was being arranged. The bullet entered the left cheek and buried itself in the tissues slightly below, where it is now encysted.

Cholera in Egypt.—The official cholera statistics show that during the week ending June 27th there were 1,383 new cases of the disease reported and 1,091 deaths.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the U. S. Navy for the week ending June 27, 1896: June 23d.—Assistant Surgeon S. B. Palmer, detached from the New York Laboratory, June 29th. June 26th.—Passed Assistant Surgeon George Rothganger, detached from the *Independence*, July 15th, and ordered to the *Oregon*.

The New Jersey State Medical Society, at its annual meeting which closed at Asbury Park on June 24th, elected the following officers: *President*, Dr. F. J. Smith, Bridgeton; *First Vice-President*, Dr. D. C. English, New Brunswick; *Second Vice-President*, Dr. C. R. P. Fisher, Bound Brook; *Third Vice-President*, Dr. Luther M. Halsey, Newark; *Corresponding Secretary*, Dr. E. L. B. Godfrey, Camden; *Recording Secretary*, Dr. William Pierson, Orange; *Treasurer*, Dr. Archibald Mercer, Newark; *Prize Essayist* for 1897, Dr. Harris. The subject for the fellows' prize essay for the coming year is the "Antitoxin Treatment of Tetanus." The next annual meeting will be held in Atlantic City in June, 1897.

The Fourth of July in Berlin.—The American physicians and dentists resident in Berlin propose to celebrate the Fourth by holding a picnic at Grunau after attending the official reception which is to be given by United States Ambassador Uhl.

Professor Edwin Klebs has been elected to the chair of pathology in Rush Medical College.

Rush Medical College of Chicago.—This college has recently been recognized by the examining board

of the Royal College of Physicians and the Royal College of Surgeons of London, England. This recognition entitles its alumni to all the privileges accorded to the graduates of other institutions recognized by that board.

Medical Association of Baltimore and Ohio Railway Surgeons.—The semi-annual meeting of the Medical Association of Baltimore and Ohio Railway Surgeons was held at Philadelphia on June 23d and 24th, Dr. J. M. Spear, of Cumberland, Md., presiding. An address of welcome was delivered by Dr. W. W. Weaver, chairman of the committee of arrangements. Among the communications presented were the following: "A Clinical Study of the Ophthalmic Symptoms in a Case of Fracture of the Anterior Base of the Skull," by Dr. Charles A. Oliver; "Fracture of the Elbow-Joint," by Dr. B. J. Byrne, of Ellicott City, Md.; "Legal Surgery," by Dr. S. S. Good, of Myersdale; "Fractures," by Dr. W. E. Stothers, of Wheeling, W. Va.; "Color Blindness," by Dr. Charles A. Oliver; "The Best Form of Amputation for Stumps," by Dr. J. M. Thorne, of McKeesport; "Fracture of the Thigh," by Dr. J. F. Reger, of Littleton, W. Va.; "The Railway Surgeon," by Dr. J. W. Wright, of Columbus. A demonstration of making tablets and an address on their use were given by Dr. J. J. Hamilton, of La Paz, Ind. It was decided to hold the next meeting at Chicago in December, 1896.

American Dermatological Association.—The next annual meeting of this association will be held at the Hot Springs of Virginia September 8, 9 and 10, 1896. Several papers on interesting subjects have been already promised. Dr. White, of Boston, will open a general discussion on the subject, "What Effect do Diet and Alcohol have upon the Causation and Course of the Eczematous Affections and Psoriasis?" The secretary of the association is Dr. Charles W. Allen, 126 East 60th Street, New York City.

Obituary.

EDWIN D. RAMSDELL, M.D.,

NEW YORK.

DR. EDWIN D. RAMSDELL died at his home in this city on Friday morning, June 12th, from pneumonia, after an illness of only three days. Dr. Ramsdell was born in Belleville, Jefferson County, N. Y., March 19, 1830. He received his education in the public schools of Watertown. When but sixteen years old he became a teacher and continued in this work for four years, and then came to New York, where he entered the Medical School of the University of the City of New York. He was graduated in 1855, and at once began practice in this city.

Dr. Ramsdell was a member of the Medical Society of the County of New York. He leaves a widow and four children, a daughter and three sons, one of the latter a physician in this city.

All who knew him revered him for his honesty of purpose, his simple life, his fidelity to all trusts, and his charity toward the poor. He never strove for honors or preferments or riches, but strove ever to do his duty to all, and he received his reward in the devoted love of his patients.

Society Reports.

AMERICAN ORTHOPÆDIC ASSOCIATION.

Tenth Annual Meeting, Held in Buffalo, May 19, 20, and 21, 1896.

ROYAL WHITMAN, M.D., OF NEW YORK, PRESIDENT.

First Day—May 19th.

The Rationale of Gymnastic Exercise and Pressure Correction in the Treatment of Scoliosis.—DR. L. A. WEIGEL, of Rochester, read a paper with this title, and summarized his views as follows: (1) Gymnastic exercise as an exclusive method of treatment must be limited to the very early stages and to deformities which are postural, pure and simple; (2) exercises of all kinds are insufficient, even in comparatively mild cases; (3) treatment by mobilizing the spine should precede any attempt to develop the muscles; (4) removal of the superincumbent weight is the important part of the treatment and is of great value in sustaining the effects of exercise; (5) overdevelopment is to be avoided; and (6) empiricism should have no part in the treatment of scoliosis.

The Rapid Cure of Rotary Lateral Curvature of the Spine and Other Postural Deformities, by Means of Thorough Development and Corrective Exercises with Heavy Weights.—DR. JACOB TESCHNER, of New York, present by invitation, read a paper on this subject and gave a demonstration of the method of carrying out these exercises. According to his view of lateral curvature, it was due to general muscular weakness and habitual faulty position, and hence the whole muscular system should be developed. At each visit the patient is put to his individual limit, and it is found that this usually increases at each visit. He claimed that by this method he had succeeded in curing cases of lateral curvature in which there were bony and ligamentous changes and marked rotation present. In the milder cases improvement was quite noticeable within two weeks, and a cure would often be effected in three months. He said that out of twenty-one cases treated by him according to this method, nineteen had been cured, and two had been very much improved at the time the treatment had been discontinued. The advantages claimed for the treatment were: (1) The improvement in the general health and in the muscular development; (2) a marked increase in the lung capacity; (3) a slower and more forcible heart action; and (4) that long after the cessation of the treatment an improvement was noted in the muscular system and in the general health.

DR. S. KETCH, of New York, in opening the discussion on the foregoing papers, said he agreed with Dr. Weigel, except that he would attribute some benefit to will power. Regarding Dr. Teschner's paper, he would say that he was not yet convinced that it was necessary or even advisable to subject children and adolescents to such a severe course of gymnastics—indeed, he believed that the cases cured by this method could be treated with equal success by other and safer means. It was not difficult to secure an improvement in cases of lateral curvature by correcting the postural curves, but the only test of marked benefit or of cure was the amelioration of the element of rotation. In his opinion it was important to increase and to maintain the lateral flexibility of the spine, and hence he would look upon the best method of treating lateral curvature of the spine as that one which combined the use of mild gymnastics and the application of retentive apparatus.

DR. JOHN RIDLON, of Chicago, said that he had tried these heavy exercises on only one patient, a girl of six-

teen. This girl became greatly fatigued after making ten or fifteen movements with dumbbells weighing one and one-half pounds, and it was impossible to get her to put up a five-pound bell more than five times. As there was no visible improvement after four or five weeks of this exercise, he had abandoned further trial of the method.

The speaker then proceeded to criticise the incomplete and inaccurate photographic records presented by Dr. Teschner, objecting particularly to the absence of photographs of cured cases and also of the best position the patient could be made to assume prior to the treatment. Without these, he said, it was impossible to judge of the merits of the method.

DR. REGINALD H. SAYRE, of New York, said that he could not accept the statement that development of one part of the muscular system must necessarily be at the expense of the remaining portion. In his opinion there were many cases of lateral curvature which could not be well treated without mechanical appliances. If it were a fact that bone changes could be made to disappear by muscular exercise alone, it was certainly a novel and wonderful scientific fact. Until indisputable evidence to this fact were forthcoming, he could not but be in doubt regarding the kind of cure meant. Nor could he accept the statement that the improvement in muscular development continued after cessation of the exercises, for this was at variance with general principles.

DR. A. J. STEELE, of St. Louis, said that he thought there was enough in Dr. Teschner's method to justify him in continuing his work along this line. He could not agree with Dr. Weigel that the spine could not be rendered flexible by means of jackets and similar appliances.

DR. HARRY M. SHERMAN, of San Francisco, said that while he agreed with those who considered the superincumbent weight the chief etiological factor, he could not but wonder why any bone in the body should be abnormally weak, unless, possibly, as a result of rickets in early life. He endorsed the use of mirrors as an aid to the proper performance of gymnastic exercises.

DR. A. E. HOADLEY, of Chicago, said he considered the prime etiological factor to be "cellular tension" or debility. Such a condition, when present in the intervertebral cartilages, may result in marked shortening of the stature. He had known this to amount to as much as one and one-eighth inches between the time of rising and going to bed at night. When such shortening exceeded half an inch deformity was invited.

DR. W. E. WIRT, of Cleveland, said that he agreed with Dr. Teschner regarding the increased flexibility of the spine produced by these heavy exercises, but he thought it was a mistake to pin one's faith on one method of treatment exclusively.

DR. HANNA, of Oberlin College, said that in the treatment of cases of lateral curvature he preferred massage to forcible manipulation, together with the use of the hot and cold douche.

DR. WEIGEL said that he did not believe that the disadvantages of mechanical supports were as great as had been claimed. He could not believe, as Dr. Teschner had stated, that the muscular strength was increased from visit to visit by the heavy gymnastics.

DR. TESCHNER, in closing the discussion, said he admitted the inaccuracies of his records, as of all known methods of recording such cases, but they were the best obtainable under the circumstances. He had made no attempt to pose his patients for their photographs.

Spontaneous Dislocation of the Hip.—DR. WILLIAM J. TAYLOR, of Philadelphia, reported a case of spontaneous dislocation which had evidently occurred about six months after a fall. The history clearly in-

licated that it was not a case in which the dislocation had been produced by the injury and had been merely overlooked. As the dislocation had existed for fifteen years before coming under his observation, no attempt had been made to dislodge the head of the femur from its position on the dorsum of the ilium.

DRS. R. H. SAYRE, GOLDTHWAIT, and RIDLON reported similar cases.

The Anterior Transverse Arch of the Foot.—DR. JOEL E. GOLDTHWAIT, of Boston, said that the cases of abnormality of the anterior transverse arch of the foot might be divided into two groups, viz.: (1) The relaxed form; and (2) the rigid type with distinct bony change. A patient having stated that the foot was becoming wider, an examination showed a callosity under the head of the second, third, or fourth metatarsal bone. The speaker thought that improper shoeing was largely responsible for the condition.

In the treatment of the relaxed form, it was most important to strengthen the front part of the foot by appropriate balancing exercises, and to relieve the strain on the ligaments and muscles by the application of a snugly-fitting bandage just behind the head of the first metatarsal bone. Immediate relief would follow the application of a pad of felt so as to make pressure just back of the heads of the second and third metatarsal bones.

DR. KETCH referred to a case in which the gouty diathesis rather than bad shoeing had caused the condition.

DR. E. H. BRADFORD said that by means of the rubber bandage and felt pads he had relieved many cases. He had seen no case of true metatarsalgia in which the second metatarsal bone was depressed; this condition was confined to cases in which the trouble was in the fourth metatarsal bone.

DR. J. E. MOORE, of Minneapolis, said that he had met with this condition most commonly among nurses. His treatment had been successfully carried out along the lines recommended in the paper.

DR. KERR, of Washington, D. C., said he also had found metatarsalgia associated with depression of the fourth metatarsal bone, and had relieved the pain and disability by excision of the metatarsal joint and sometimes also of the nerve.

THE PRESIDENT called attention to the fact that a proper shoe should be made so that the toes do not point upward, as they did in the ordinary shoe.

DR. GOLDTHWAIT, in closing, said that undoubtedly the chief cause was bad shoeing. In some cases there had been pain at the head of the fourth metatarsal bone, and in others between the second and third metatarsals.

The President's Address.—The subject of this address was "The Definition and Scope of Orthopædic Surgery." DR. WHITMAN suggested the following definition: "Orthopædic surgery is that division of surgery which treats of disabilities and diseases of the locomotive apparatus and of the prevention and treatment of the deformities of the framework of the body."

Investigations on Flat Foot.—DR. E. H. BRADFORD, of Boston, by means of lantern slides, showed the development and causation of flat foot. These photographs compared the weak feet of shoe-wearing people with the strong feet of those who were accustomed to go about without shoes.

DR. WHITMAN commented upon the evident advance that had been made in the last decade in the knowledge and therapeutics of this subject.

Second Day—May 20th.

The Treatment of Abscess in High Dorsal Caries.—DR. E. H. BRADFORD, of Boston, in a paper with this title, advocated operation and drainage of the ab-

scess. This operation should be begun, he said, by cutting down upon the tip of the transverse process and resecting a portion of rib, after the manner of an operation for empyema. There was less danger to the heart and large blood-vessels if the incision were made on the right side.

DR. R. H. SAYRE said that Dr. Schafer, of Chicago, in some cases of this kind, had passed in a probe and cut down upon it, and had then established through drainage from one side to the other.

DR. SHERMAN said that he had performed the operation in a case in which the abscess had perforated an intercostal space and produced an accumulation under the skin. The diagnosis was comparatively easy if the way were made plain by the burrowing of the abscess between the ribs.

DR. KETCH referred to a case of very sudden death of a child suffering from disease of the second and third cervical vertebra. Although no autopsy could be obtained, it seemed fairly certain that death had been due to the direct pressure upon the respiratory centre.

DR. GOLDTHWAIT said he had seen the suddenly fatal case which had formed the text for Dr. Bradford's remarks. The cause of the sudden death remained unexplained, for the autopsy showed that the abscess had not ruptured, and there was no evidence of pressure on the spinal cord.

DR. BRADFORD, in closing the discussion, said that when there was disease of the axis and atlas there was danger of direct pressure upon the respiratory centre, but when the disease was lower down and was associated with suffocative symptoms, it was fair to conclude that an abscess is present. The operation which he had advocated was certainly a grave one, but it was intended to meet a grave emergency.

Suppuration in Joint and Spinal Disease, and Its Relation to Tuberculous Meningitis.—DR. SAMUEL KETCH read a paper with this title.

DR. J. E. MOORE said he thought it might be safely concluded that the formation of tuberculous abscesses did not play a very important part in the development of tuberculous meningitis. The evidence in the paper would also seem to point to the fact that operative measures were much less likely to cause tuberculous meningitis or general tuberculosis than had been supposed.

DR. A. M. PHELPS said that he did not think it was possible for true suppuration to produce a tuberculous lesion.

DR. GOLDTHWAIT said that his cases of tuberculous meningitis had given only the clinical evidence of this disease, but in every instance the autopsy had disclosed an acute general miliary tuberculosis.

A Clinical Study of Iodoform Glycerin in Tuberculous Osteomyelitis.—DR. HARRY M. SHERMAN, of San Francisco, read a paper on this subject, based on a carefully recorded experience in twenty cases. Fifteen of these were cases of hip disease, two of knee-joint and two of ankle-joint disease, and one of disease of the elbow. In all, one hundred and sixty-four injections were made. About half of those were intra-articular and the other half were intra-osseous injections of a ten-per-cent. solution of iodoform in glycerin. In no case was there any iodoform poisoning nor was the injection the cause of suppuration in any. The action of the injections was in most instances disappointing. In no case was the orthopædic treatment interrupted.

DR. ROSWELL PARK, of Buffalo, said that he had made an extensive trial of the intra-articular injections of iodoform, but had not seen much benefit from their use. In two cases coming to excision the iodoform was found packed into a mass, which acted as a foreign body. He had made some culture experiments

with iodoform, and these had demonstrated that the germicidal power of iodoform was very feeble.

DR. J. E. MOORE said that he, too, had met with nothing but disappointment from the iodoform injections, except in the treatment of psoas abscesses. With these he thought they had been of some benefit.

DR. HENRY LING TAYLOR, of New York, said that although iodoform had proved disappointing when injected into diseased joints, he thought a solution of iodoform in ether was a valuable injection for sinuses.

DR. PARK said that as the germicidal action of iodoform was claimed to be due to the liberation of free iodine, he proposed to study the effects of injections of iodine and glycerin.

DR. JOHN RIDLON said that a sharp distinction should be made between cases treated by protective apparatus in conjunction with iodoform injections and those in which only the injections were used. He had treated about thirty cases by the intra-articular injections. About one-third had shown improvement; another third had remained stationary; and the others appeared to have been made worse by the treatment.

DR. A. M. PHELPS, of New York, said that he had used the injections of iodoform with negative results. Iodoform and glycerin were useful in tuberculous abscesses, partly because of the hygroscopic nature of the glycerin.

Further observations on the use of hydrochloric acid in bone necrosis of tuberculous origin, with report of cases were made by other speakers.

DR. JEROME HILTON WATERMAN, of Buffalo, reported his experience in the treatment of tuberculous bone necrosis by means of injections of strong hydrochloric acid. The injections were usually made twice a week. His experience was, on the whole, favorable to the method.

DR. W. R. TOWNSEND said that he had observed good results from this treatment, particularly where the necrosis was superficial.

DR. A. E. HOADLEY, of Chicago, said that the application of a five-per-cent. solution of hydrochloric acid was sufficient to quickly decalcify the bone without destroying other tissues.

DR. SHERMAN said that as the chief seat of disease was the granulation tissue in the bone, it would seem to him that the use of the sharp spoon would be more effective.

DR. WATERMAN, in closing, said that the treatment was at times quite slow. He would advise the use of a local anæsthetic in conjunction with the acid applications.

The Use of Dry Heat in the Treatment of Chronic Joint Affections.—DR. WILLIAM E. WIRT, of Cleveland, described the apparatus which he employed. It consists of a copper drum twelve inches long and nine inches in diameter, fitted at each end with a wooden ring and a hood of thick rubber. Having protected the back of the knee with cotton, it is enclosed in the apparatus and heat applied to the outside by means of a Bunsen burner. Most patients would tolerate a temperature between 250° and 300° F., provided three holes were made in the drum to secure proper ventilation and so keep the air dry. This treatment gives an immediate relief to pain and increases temporarily the mobility of the joint.

Division of the Hamstring Tendons by the Open Method for Correcting Malposition and Securing Rest in Tuberculous Disease of the Knee.—DR. BERNARD BARTOW, of Buffalo, in a paper with this title, contended that division of the hamstrings gave quicker relief and secured better rest than did mechanical appliances, and that it cut short the inflammatory process. The operation should be done by open incision.

DR. WIRT thought it was rare that mechanical means would fail to straighten these cases.

DR. R. H. SAVRE said that the operation might be occasionally demanded, but whenever possible the straightening should be accomplished by mechanical treatment alone.

DR. B. E. MCKENZIE, of Toronto, said that he considered the method unjustifiable until after mechanical treatment had failed, and in his experience mechanical means had never failed under such circumstances. He thought that the patients just exhibited should not be allowed to go around without better protection of the joint.

DR. JOHN RIDLON, of Chicago, was very positive that any joint still diseases could be straightened without operation. He was accustomed to use some form of a Thomas brace. In cases in which the greater part of the rigidity appeared to be due to fibrous adhesions and muscular shortening, without evidence of acute inflammation, he would straighten the limb by manual force applied under anæsthesia.

DR. W. E. WIRT, as an example of what could be accomplished by mechanical means alone, referred to a recent case which had been pronounced by several surgeons to be one of bony ankylosis, yet he had succeeded by mechanical measures alone in straightening the limb in two months.

DR. BARTOW, in closing, said that to insure safety and thoroughness the operation of dividing the hamstrings should be done through an open incision. In the cases that he had treated by the method described in the paper he knew of no other alternative than excision; hence he considered the division of the hamstrings perfectly justifiable. The method was intended as only one means of accomplishing an end.

A Theory of the Ultimate Etiology of Deformity, and its Practical Application.—DR. ROYAL WHITMAN said that in the process of evolution the erect posture had been comparatively acquired, and that it was an attitude difficult of acquirement and difficult to maintain. The ordinary so-called postural deformities were then explained. The flexion and contraction deformity, he said, was of special interest to the orthopaedic surgeon. If one accepted the morphological theory of its etiology, it would be evident that as the erect posture was a newly-acquired attitude, so also the uses by the limbs proper to that posture were newly acquired. Complete extension of the limb in the support of this posture required not only the greatest expenditure of nervous energy but also the greatest strain upon the joint surfaces, and when the ability to assume this attitude became impaired the affected member became flexed; in other words, it involuntarily assumed an attitude common to the lower or quadrupedal form of locomotion. Flexion was an evidence of unbalanced nervous influence and of preponderance of power of the lower or reflex centres. In joint disease the cause was local irritation and consequent muscular spasm; in the second, the inhibitory influence of the higher centre was impaired or removed. The erect posture was an evidence of the higher position of man in the scale of evolution. When the controlling force of the higher centre was directly or indirectly impaired, the more difficult and newly-acquired attitudes were disused, and the affected part fell backward toward the type from which it had been differentiated.

Further Observations on the Cause of the Limp of Hip-Joint Disease.—DR. HARRY M. SHERMAN, of San Francisco, read a paper with this title. He said that tuberculous bone disease resulted in a wasting of the osseous trabeculae and the development of an area of structural weakness, usually in the neck of the femur. In hip disease the effort is made to bring the centre of gravity of the body as nearly as possible over the head of the femur, so as to relieve the strain put upon the structurally weak spot. This theory assumes that there is a "bone sense," comparable to

the muscle sense. The speaker then went on to describe by the aid of blackboard diagrams his mechanical theory of the causation of the limp of hip-joint disease. He endeavored to show that the keynote to the subject, from a mechanical point of view, was the fact that the head and neck of the femur constitute a column and bracket, or what is known in mechanics as a cantilever, and that these anatomical members were, therefore, governed by the same mechanical laws as control the operation of the cantilever.

DR. WIRT said that he believed the author was in the main correct in his theory, but he would remind him that when running the femur supports the weight of the body plus the momentum.

DR. A. M. PHELPS said that he was of the opinion that the capsule of the joint was swollen with tuberculous material, and that as a result, in order to relieve intra-articular tension, the patient pulled the limb into a partially flexed position.

DR. BRADFORD said that in some cases the lack of free motion in the joint would account for part of the limp. In cases of cured hip disease with the limb much adducted, the limp was often due to the effort of the patient to balance himself.

THE PRESIDENT said that the weak point in the author's argument was the assumption of voluntary adaptation of the limb. If this were voluntary one would certainly not expect it to occur in very early infancy, and yet it was known that the limb assumed such a position in these patients.

DR. WEIGEL said that he would like an explanation of the fact that in the early stage there would be a limp even though there had been no swelling of the joint. Again, Dr. Judson had shown that patients who had recovered from hip disease and who still limped, could be trained until the limp was scarcely noticeable.

DR. SHERMAN said that in running the footprints were very nearly in a straight line, thus bringing the point of support nearer to the centre. This was not a voluntary but a reflex act. He believed it was rare for hip-joint disease to begin in the capsule. The recovered patients who walk without limp are those in whom there is ankylosis between the bones.

Femoral Osteotomy for Correction of Hip Deformity in Adults.—DR. A. R. SHANDS, of Washington, D. C., read a paper in which he advocated Gaunt's intratrochanteric osteotomy. He preferred to do this operation with Gaunt's osteotome having a blade only three-fourths of an inch wide. The only dressing was sterilized gauze retained by adhesive plaster and a plaster-of-Paris spica applied after a proper position of the limb had been secured.

DR. PHELPS said that he would advise in a case of double hip-joint disease with ankylosis the performance of excision, care being taken to remove enough bone to prevent ankylosis. He had recently adopted a novel method of securing motion at the joint, viz., cutting through just above the lesser trochanter, bringing down the limb by force, cutting off about three-fourths of an inch of the femur, and then inserting a piece of fascia between the ends of the bones.

DR. SHERMAN said he would limit this subtrochanteric osteotomy to cases in which there was no motion between the femur and pelvis.

DR. W. R. TOWNSEND referred to several adult patients coming under his observation, in whom an excellent result had been obtained by operation for bony ankylosis.

DR. GOLDTHWAIT also cited several adult cases, and remarked that in these cases the limb had been put up with ten or fifteen degrees of flexion, so as to make it more comfortable for the patient when sitting down.

DR. J. E. MOORE said that while the result was not so likely to be good in cases in which there was some

motion, he would not confine operation entirely to those cases in which there was complete bony ankylosis.

Osteo-Sarcoma of the Hip.—DR. ARTHUR J. GILLETTE, of St. Paul, reported three cases illustrating the difficulties in differential diagnosis when there was osteo-sarcoma of the hip. Deformity might not occur for months after the onset of the disease, and there would be in all probability no fixation, very little atrophy, and little or no shortening.

DRS. R. H. SAYRE, SHERMAN, and MOORE also reported similar cases.

Tuberculosis of the Wrist.—DR. JAMES E. MOORE, of Minneapolis, read a paper on this subject. He said that wrist-joint disease comprised about five per cent. of all tuberculous joint diseases, and occurred most commonly in persons between fifty and sixty years of age. The disease was insidious in its development, but the diagnosis could be easily made by the swelling, atrophy, flexion, and the peculiar position of the thumbs and fingers. The tendon sheaths were often involved. Children often recover from the joint affection, but rarely live to maturity; in adults it almost invariably ends in phthisis. For children, enforced rest of the joint by means of plaster-of-Paris dressings is of service; but for adults it is applicable to recent cases only, and should then be combined with injections of iodoform emulsion. When there were sinuses and evidence of suppuration, the choice lay between complete excision and amputation. Amputation was often the most conservative treatment. The author did not favor early excision, because the functional results were bad, and as a life-saving measure it could not compare favorably with amputation. When the disease was well marked and progressing rapidly, when there was well marked wrist-joint disease with incipient phthisis, and when with the wrist-joint disease there was advanced pulmonary tuberculosis, he would recommend amputation.

DR. MCKENZIE said that he had had some very good results in this class of cases from the use of injections of iodoform and glycerin. He had not observed severe reaction following this treatment; indeed, in some instances the existing pyrexia had been observed to diminish after the injections.

DR. SHERMAN commended amputation as the best treatment in cases of severe disease of the wrist.

DR. GILLETTE said that some of those who had spoken had implied that these patients suffered much pain. His own impression had always been that wrist-joint disease was associated with very little pain.

DR. MOORE, in closing, said that occasionally pain was prominent. In one case he had done an amputation because of the intense pain, and the result, both as regards prolongation of life and increased comfort, had justified the amputation.

The Mechanical Treatment of Ingrown Toe Nail.—DR. HENRY LING TAYLOR, of New York, read a paper in which he recommended the following method, modified from that devised by Mr. Masters, of England: A flat strip of silver, one-one-hundredth of an inch thick, and one-eighth of an inch wide, and one inch long, is bent into the shape of a fishhook. The toe having been cleansed with peroxide of hydrogen and moistened with a solution of cocaine, the hook is inserted under the lateral edge of the nail so that the shank of the hook curves over the side of the toe and lies close to it. The greater the ulceration the less the pain in inserting the hook. It is retained in place by adhesive plaster or a bandage. The hook not only protects the flesh from the nail, but it exerts a lifting action on the nail. After a few hours the patient suffers no inconvenience from the hook, and in a few days the swelling subsides and the granulations become more healthy. It is well to wear the hook for

several weeks after the tissues have healed, in order that they may become sufficiently hardened. The method, the speaker said, was applicable to the severest cases.

—
Third Day—May 21st.

Mechanical Support for Flat Foot.—DR. J. C. SCHAPPS, of Brooklyn, described a method of making steel soles for flat feet. On hammering out by hand a steel sole to conform to the arch of a well-developed adult foot, it would be observed that the anterior and posterior halves were nearly alike. Having modified the sole plate so as to make these the same, it was found that the shape resembled that of a portion of the convex surface of a cone, with the apex directed toward the outer side of the sole and the base toward the inner side of the foot. From this plate plaster casts were made, and these casts served as models from which iron dies were manufactured. With such dies any mechanic could make steel plates, from which soles were easily cut for right or left feet, high or low, large or small feet. A contour of the patient's foot is taken on cardboard and trimmed to fit the sole of the shoe in front, outer side, and back, and is made wide enough to allow of it coming well up on the inner side of the foot at the arch. This pattern is used to correct the rough outline of the foot taken on the plate itself. The curved line representing the inner edge of the arch of the plate should be located just below the scaphoid and the head of the astragalus. The inner flange of the plate requires careful shaping; it should be nearly vertical as the patient stands on the plate. Having fitted the plate to the foot and to the shoe, it should be covered with vulcanized rubber.

Apparatus for the Treatment of Pott's Disease.—DR. SCHAPPS also presented a wheel cot which he had found useful for the purpose of maintaining uninterrupted recumbency with regulated pressure in Pott's disease. Traction could also be applied. He said that the energy required to hold the spine rigid and the lower limbs in a continuous state of elastic tension to break the shock to the spinal column, exhausted the general and local recuperative forces. It was injurious, in his opinion, to interfere with the respiratory movements of the chest and abdomen. The sternum should be used as a base from which to make forward pressure on a dorsal kyphos. It was also apparent that both the posterior or spinal and the anterior or sternal supports of the upper mass should be kept under it, and lateral pressure on the chest avoided. For the treatment of Pott's disease in the upright position the author used a combination of the Taylor brace posteriorly and anteriorly a rigid light support which made pressure only on the parts which could convey it to the spine without interfering at the same time with respiration.

The Treatment of Pott's Paraplegia.—DR. LE ROY W. HUBBARD, of New York, in discussing this subject and reporting two cases, asked if it were possible to reduce the period of paralysis. After reviewing the history of the treatment of this very common complication, and reading replies received from a circular letter that he had sent to the members of the association, he concluded that if immediate efficient mechanical support were applied to the spine, absolute recumbency enforced until power returned, and a general tonic plan of treatment were carried out, there would be a complete cure in almost every instance, and in the majority in a short time. Operative treatment was very rarely called for.

DR. KETCH said that his experience did not show a natural tendency toward recovery in cases in which the paraplegia affected the arms.

DR. WEIGEL said that it had been his lot to deal

more especially with cases of adults, in whom the prognosis was relatively less favorable. He did not think any one could give even an approximate idea regarding the average duration of Pott's paraplegia.

DR. RIDLON said that his experience had been that the cases in which the sphincters were involved gave the worst prognosis. In one case in which the arms had been affected recovery had been quite rapid.

Congenital Defects of the Long Bones.—DR. B. E. MCKENZIE, of Toronto, presented a number of specimens and reported upon ten cases of such defects.

Congenital Club Hand.—DR. C. E. THOMSON, of Scranton, present by invitation, reported a successful operation on a case of this kind, occurring in a girl of thirteen, who belonged to a rather remarkable family of children with congenital deformities.

The Treatment of Club Foot.—DR. A. M. PHELPS, of New York, said that the treatment of club foot by manipulation and retentive dressings should be begun at the earliest possible moment, and when after a reasonable time the progress by this method became very slight, all parts offering resistance to reduction of the deformity should be cut and the limb put up in a super-corrected position. Out of three hundred and forty-three operations he had had only five per cent. of relapses, and in the last series—one hundred and eighty-two cases—there had been no mortality.

Dislocation of the Patella Treated by Operation.—DR. JOEL E. GOLDTHWAIT, of Boston, presented a report upon this subject.

Torticollis Due to Adenoid Vegetations and Chronic Hypertrophy of the Tonsils.—DR. ARTHUR J. GILLET, of St. Paul, reported three cases, two of them being congenital. In one of the cases the removal of the adenoid vegetations was sufficient, without any division of the sterno-mastoid or other treatment, to effect a prompt cure.

DR. SAMUEL KETCH, of New York, was elected president of the association for the ensuing year.

ILLINOIS STATE MEDICAL SOCIETY.

Abstract of the Proceedings of the Forty-Sixth Annual Meeting, Held at Ottawa, May 19, 20, and 21, 1896.

THE society met in the First Baptist Church, and was called to order by the president, DR. D. W. GRAHAM, of Chicago.

DR. C. W. HALL, of Kewanee, offered the following resolution, which was unanimously adopted:

"Whereas, Resolutions concerning vivisection were passed by the American Medical Association at Atlanta; therefore be it

"Resolved, That the resolutions mentioned and published in the *Journal of the American Medical Association* express the sentiments of the Illinois State Medical Society, and that our secretary be requested to send copies of these resolutions to the members of Congress from our State."

The first paper read was by DR. E. FLETCHER INGALLS, of Chicago, entitled

Orrhotherapy in Diphtheria.—The author stated, at the outset, that as a result of the work of Pasteur and the numerous investigations which have followed in the same line, it is now generally believed by bacteriologists that many diseases, especially those which seldom affect individuals more than once, are self-limited by the formation within the blood of a product capable of destroying the toxic material that excites the disease; hence called antitoxin. In such diseases, if life be prolonged until a sufficient quantity of the antitoxin has been developed, the toxic agent is de-

stroyed and recovery follows if no serious complications have arisen.

Coming to the question of diphtheria, he said that the diphtheritic poison had been introduced into animals, preferably into the horse, until immunity to its further effects had been obtained. The animal was then bled, the blood allowed to separate, and the serum preserved under the name of antitoxin.

Attached to the paper was a table showing a large percentage of complications after the antitoxin treatment. By far the most frequent complication was a rash, usually urticarial, sometimes erythematous, or having the appearance of scarlatina. A rash was observed in 45.9 per cent. of all cases. This was accompanied by fever in many cases, amounting to 29.6 per cent. of the patients presenting a rash. In some instances the rash persisted for many days, but usually it had run its course by the end of the third or fourth day. There were a few instances of effusion into the joints, and abscesses were found at the site of injection in 2.3 per cent. of the cases.

Dr. Ingals closed thus: "Until more definite information is obtained conservative physicians may well be excused for declining to experiment with this remedy upon their patients; however, the wide belief that it does much good and the comparatively certain knowledge that it does but little harm, suggests that our duty to our patients demands that when diphtheria exists we should administer the antitoxin if it is desired, but that at the same time we should use such other remedies as have been proven of most value in combating this disease; but we should hesitate to recommend it as a prophylactic measure. We believe that experimentation in the treatment of diphtheria by serum is in the right direction, and we hope that the enthusiastic friends of orrhoterapy may be largely vindicated; yet we cannot search far into the history of medicine to find that very many of the remedies now employed have in the beginning been lauded excessively, and that not a few of those that were formerly supposed to be extremely efficacious have been found to be practically worthless."

Treatment of Tuberculosis was the title of a paper read by DR. N. S. DAVIS, JR., of Chicago, in which he said that the establishment of serum antitoxin as a successful remedy for diphtheria by the elaborate experiments of Behring, Kitasato, and others, suggested the employment of serum prepared by analogous methods for tuberculosis. Tuberculin and the products derived from it had fallen into almost complete disuse. A few still employed them. Serum was employed as a cure for tuberculosis in 1890. Recently serum from horses, made immune to tuberculosis by inoculations successively with viruses of gradually increasing virulence, has been prepared and tried independently in Italy, France, Austria, and in this country. Good results are reported with much uniformity from the employment of this serum in cases that are not complicated by serious infection with other microbes than the tubercle bacillus. The ordinary dose is 2.5 cubic centimeters, administered hypodermatically daily or every second day. Much larger doses have been employed, but not with proportionately better results. The heart and arteries are not affected by these injections. A leucocytosis follows them. Increase in the number of red blood corpuscles and hæmoglobin occurs as general improvement takes place. As a rule the urine is not materially modified. In a few instances albuminuria and peptonuria have been provoked, but no serious lesion of the kidneys. Appetite is almost uniformly improved after the first few injections, and increase in bodily weight rapidly follows.

The author's experience with this treatment is limited to a single case now under observation, and from

it he says he cannot yet draw conclusions. The treatment seems to be harmless and in suitably selected cases to promise improvement. Much more time must elapse before we can with confidence pronounce such improvement a permanent cure.

DR. JAMES B. HERRICK, of Chicago, read a paper entitled

Therapeutic Uses of the Thyroid Extract.—He reviewed at considerable length thyroid therapy and presented the conclusions that one feels justified in drawing from a study of the results already accomplished by the employment of this remedial agent in various diseases. He drew the following deductions concerning thyroid extract:

1. It is curative in myxœdema (idiopathic, cretinism, operative).
2. Many cases of obesity are cured by it.
3. Simple hyperplastic struma, particularly in the young, is frequently cured or improved.
4. In 1, 2, or 3, the remedy has to be continued for an indefinite time in order to prevent relapse.
5. It may prove of value in some cases of tetany.
6. In skin diseases it is of doubtful value, to say the least.
7. The same is true of mental and nervous diseases.
8. In exophthalmic goitre it is contraindicated.
9. The results are practically the same whether fresh glands, extracts, or dried glands are employed.

This is probably true also of the thyroidin of Baumann.

Home Cure and Treatment of Epileptics.—This paper was read by DR. A. L. WARNER, of Kankakee. After giving an outline of epilepsy the author stated that the percentage of complete recoveries from this disease was small, owing to its obscure nature and to the fact that only in a small number of cases does treatment seem to have more than a palliative action.

In referring to the preventive treatment, he called especial attention to the fact that even slight head injuries may sooner or later become active factors in the causation of epilepsy, and such injuries should be closely examined and receive proper treatment, not only for the injury itself but to prevent the possibility of a person becoming subject to epilepsy at a future time.

The treatment of epilepsy resolves itself into: (1) The treatment of convulsive seizure; (2) treatment—medical, hygienic, and surgical—to prevent the recurrence of seizures; and (3) treatment of complications.

The surgical treatment has come more prominently into use during the past two years. Under aseptic conditions, trephining for the elevation or removal of depressed bone has become common, and even excision of portions of the cortex of the brain have been made by some with the view of destroying the supposed explosive centre. Operations for the removal of diseased tissues and meningeal and brain tumors have also been followed frequently with good results.

Finally, he said that it was to be regretted that the progressive State of Illinois has not yet provided a hospital for epileptics, where they would be cared for and treated in a systematic manner by physicians and nurses who make a specialty of this disease, and, in the event of its being of an incurable nature, would have a home provided by the State in which they may have comforts and surroundings suited to their peculiar needs.

Hystero-Epilepsy.—This paper was read by DR. HUGH T. PATRICK, of Chicago, in which he first defined hystero-epilepsy as not epilepsy in any sense of the word, but hysteria pure and simple. He then proceeded to describe a typical paroxysm of hystero-epilepsy, an attack which he said is rarely seen, but serves well as a basis for the description of the incomplete or aberrant forms which are of frequent

occurrence. The different periods and substages were accurately described and illustrated by a number of well-executed drawings. He showed that in an attack of hystero-epilepsy there is nothing after the first or epileptoid period that in the least resembles epilepsy. A patient who struggles, has to be held, who makes exclamations, tears the bedding, or tries to bite himself or others, is not an epileptic. A patient who shows marked opisthotonos, rolls over and over, or performs acrobatic feats, is not an epileptic. A patient who assumes striking postures or shows exalted psychic action during the attack is not an epileptic. An attack that lasts fifteen minutes or more is not epilepsy.

Dr. Patrick then gave in detail the points in the differential diagnosis between an hysterical attack closely simulating epilepsy and true epileptic convulsions.

In conclusion, he insisted that hysterical convulsions are not confined to Paris and the Salpêtrière, but are of rather frequent occurrence in this country in the small towns, as also in the large cities. He has seen in the last few months a number of cases of hysterical convulsions which had been thought to be epilepsy and had been treated as such for various lengths of time.

DR. J. B. MAXWELL, of Mt. Carmel, read a paper entitled

Status of Epileptic Legislation.—Among the special reasons for the establishment of a colony of epileptics he gave:

1. For the welfare of the epileptics, whose numbers justify the outlay.
2. For the welfare of the insane, who should not be compelled to associate with them in the hospitals.
3. To diminish so far as possible the overcrowding of hospitals for the insane.
4. To remove the epileptics from the almshouses, where it is a hardship for many of them to be, as under favorable circumstances they would be able to work and might be restored to health.

The benefit that must accrue to epileptics in particular and to society in general would be very great, and scores if not hundreds who now refuse to enter the dark portals of the hospitals for the insane or the forbidding gates of the institution for the feeble minded would be glad to enter the home or colony for epileptics. The speaker is convinced that too much time has already been lost, and he strenuously recommended immediate legislation in behalf of epileptics.

The president, DR. D. W. GRAHAM, of Chicago, delivered the annual address. He selected for his subject the

Mutual Relations of the Medical Profession and the Public.—He said that the reciprocal relations and duties of the medical profession and the community were a theme like an old jewel, which required an occasional resetting to bring it into harmony with the changes of time and circumstance. The medical profession, as one of the constituent parts of the community, has intimate relations to every other interest and part of that community. Its work and the principles which it represents are in their importance to organized society second to no other. Through medical science the profession has a twofold relation to the community at large. First, that in which the physician lives for himself; second, that in which as a benefactor he contributes to the welfare of others, in which he is the exponent of all that medical science means to men. By and through it he earns his living as a citizen, discharges his first duty to himself and others both in point of time and importance.

There were rewards other than pecuniary which were due the physician from the community, and of which he was sometimes deprived. It was due to the dignity

of his calling and in the interests of the highest usefulness of the profession to the public that all positions of honor, profit, or trust, whose chief functions pertained to medical matters and required medical knowledge for their administration, should be held by physicians.

A confusion of values in the mind of the public and to some extent in the mind of the profession, has arisen in these latter days with respect to remuneration. This, Dr. Graham thought, was partly due to the exuberant specialism which characterized modern medicine. It was also partly due to the greater advance and wider scope of operative surgery, and in part to the relatively unimportant rôle which the internal treatment of disease by drugs has assumed in comparison with former times. There never was a time when the drug treatment of disease could accomplish more than to-day, when internal medication was more definite in its results, though its limitations are better recognized than before. While in former times it outranked in importance all other means and methods, to-day preventive medicine and operative surgery have outstripped it in the general advance in demonstrable results.

The medical profession has a standing grievance against the community, in that the pretender, the unscrupulous, and the ignorant so often received the encouragement and the reward which rightly belonged to the qualified, educated physician.

A government which spends eighty million of money a year on its army and navy in times of peace, one hundred and fifty million in pensions, sixty million on its inland rivers and harbors, and many million more to promote commerce and other material interests of its people, ought to spend more than one or two hundred thousand dollars a year in the interests and in the name of the health of all the people. This small pittance which is now expended in this direction is spent in the name and for the sake of trade and commerce by the marine hospital service for the purposes of quarantine, one of the subordinate functions of this department, which is itself a subordinate department of the executive branch of the government.

Coming to the question of medical legislation, Dr. Graham said that a sprinkling of intelligent medical men might improve a legislature. It could not affect it seriously otherwise. When medical men are willing to take part in public affairs, instead of staying at home and grumbling and writing jeremiads, medical questions may be better treated in legislative assemblies.

DR. HAROLD N. MOYER, of Chicago, followed with an address entitled

Needed Medical Legislation in Illinois.—He said that medical legislation in this State has been fairly fruitful in the past. An examination of what has been accomplished, shows that existing law, while pregnant with promise for the future, is still far short of what should be. To this State belonged the proud distinction of having first placed upon its statute books a law regulating the practice of medicine. This was followed by our best piece of law making, the anatomical bill, which, as amended, is as nearly perfect as could be wished. By it anatomical study has been placed within the reach of students of medicine to a degree and with a perfection that leaves nothing to be desired.

The law regulating the admission of insane patients to our hospitals, which has been in operation for the past two years, was rendered much less effective than it otherwise would have been by a stupid amendment which has made its construction very difficult. As it was prepared by a committee of this society and submitted to the legislature, it was a symmetrical bill, providing not only for a trial by jury but also for the

appointment of a commission and for self-commitment. These were all separately described in the bill and provision made for carrying them out.

Dr. Moyer then passed on to the consideration of expert testimony, saying that it had been taken up and considered at the last session of the legislature, and a bill regulating this important branch of judicial procedure narrowly missed enactment. In his judgment this bill ought again to be brought forward and an effort made to pass it. As at present proposed, the law is restricted to expert testimony in criminal cases.

Finally, he said, the time for an examining board has arrived. This being established, the various schools could then meet on the common ground of anatomy, chemistry, pathology, bacteriology, and, above all, a thorough test of a candidate's knowledge of the English language and general scientific attainments.

Diagnosis of Typhoid Fever.—DR. C. B. HORRELL, of Colchester, read a paper on this subject. Two potent factors essential to success in a physician are a good diagnostician and a good collector. The speaker has not always found the diagnosis of typhoid fever an easy task, not even in simple uncomplicated cases. He insisted that without careful and exhaustive physical examination of the patient and investigation of his surroundings the physician was likely to be placed under the embarrassment of a mistaken diagnosis.

The Treatment of Typhoid Fever was the title of a paper by DR. JAMES P. LYTLE, of Princeton. After dwelling at considerable length upon the various treatments of typhoid fever, the author said that whatever may be our present or future treatment of this disease, good judgment and common sense in its management would ever remain the chief elements of success. The late Dujardin-Beaumez recognized this, for at the end of a busy life, full of years and good works, he left this legacy as the result of his experience: "That the best treatment for typhoid fever is a good physician."

DR. JOHN A. PRINCE, of Springfield, read a paper entitled

Pelvic Abscess.—The author dwelt upon the surgical treatment, citing a few cases that had occurred in his own practice. He believes that in nearly all cases the infection is from the tubes, and that whether the abscess is a true pyosalpinx, an ovarian abscess, or independent of the uterine adnexa, the tubes constitute the channel of infection.

The surgical treatment resolves itself into the various methods of evacuating the pus. The various methods might be classified as follows: (1) Laparotomy with extirpation of abscess mass. (2) Laparotomy with cleansing and drainage of abscess cavity. (3) Drainage by vaginal hysterectomy. (4) Drainage by vaginal incision. (5) Aspiration.

Laparotomy with complete extirpation of the pathological tissues involved in the abscess is, he thinks, the ideal method, and where practicable should be employed.

Vaginal hysterectomy for the cure of pus cases was of very recent origin, and as the speaker's experience was limited to one case he was not prepared to speak with authority.

The Necessity of Close Inspection in Head Injuries.—By DR. R. E. LEWIS, of Macomb. The author emphasized the importance of investigating every case which comes under observation. Sufficient time has now elapsed since the inauguration of operative procedures upon the cranium and brain for the cure of various mental and physical defects to allow us to judge somewhat correctly of their merits, and in looking over the reports of cases with subsequent histories in the hands of the most competent operators, the speaker was astonished to find so small a percentage of

actual cures resulting from what at first seemed brilliant and promising methods. After relating an interesting case of depressed fracture of the skull, which the author had treated successfully, he drew the following conclusions:

1. All scalp wounds will bear close inspection.
2. The troubles resulting from pressure on the brain should be removed so soon as manifest.
3. This work should be done by the general practitioner in the rural districts, as well as by the skilled surgeons in the city.

Craniotomy on the Dead Child.—DR. JOSEPH B. DE LEE, of Chicago, read a paper with this title, in which he gave the following indications for craniotomy:

1. All cases in which the child is dead give indication for the termination of labor. This operation should be done instead of using the forceps, when the maternal soft parts are unprepared for rapid delivery. Such cases are eclampsia, placenta prævia, premature detachment of the normally implanted placenta, prolapse of the cord, with danger to the mother from any cause. In short, the forceps should not be applied on a dead child. The only exception the speaker would make to this rule was the case of a multipara, with the head low down and the soft parts well prepared.

2. Cases of contracted pelvis when the conjugata vera is not smaller than two and one-half inches. To do a hard version extraction, or extraction by forceps, or a Cæsarean section, is not justifiable when the child is dead.

3. In neglected transverse presentation embryotomy should be done. The thought of a version should not be entertained for a moment.

Cleanliness in Obstetrics.—DR. EMMA B. STANDLEY, of Alexis, contributed this paper. The first step in cleanliness in obstetrics was for the physician to be clean himself when called upon to attend a woman in confinement. Her plan has always been to allow the mother to rest for a little time after delivery until the babe is attended to; then a bowl filled with warm water is brought and a disinfectant added, and the pudendum thoroughly cleansed, care being taken not to expose the patient. Another help to cleanliness in obstetrics was the rectal enema of warm water that the bowels might be thoroughly moved. This has a relaxing effect upon the sphincter ani muscle and perineum, and prepares the way for advance of the child far better than if the physician has a loaded rectum to contend with.

Hydrotherapy in the Management of High Temperature in Typhoid Fever.—By DR. GEORGE G. CRAIG, of Rock Island. He enumerated the methods generally used for applying hydrotherapy in the treatment of typhoid fever. As with any other remedy, judgment must be exercised in the selection of the mode and the manner of administering it in each individual case, bearing in mind that statistics prove that the nearer the exact technique of Brand is and has been followed the better the results. In all cases the physician could not let his views be known, but in hospital practice particularly, and in private practice when possible, the author believes that we should adopt hydrotherapy as a whole or in part.

DR. O. B. WILL, of Peoria, read a paper entitled "Some Observations Respecting the Etiology of Ectopic Pregnancy."

Surgery of the Gasserian Ganglion.—DR. J. B. MURPHY, of Chicago, followed with a demonstration of the surgery of the Gasserian ganglion, and reported cases. He confined himself almost exclusively to the technique of the more recent operation, after reviewing the results of previous operations for the removal of the ganglion. Internal medication and anodynes had absolutely failed to permanently relieve the intract-

able neuralgias of the face. Reference was made to the methods advised and advocated by Rose, Horsley, Andrews, and others, for the removal of the ganglion. Dr. Murphy then described in detail and illustrated a slightly modified technique of the Frank Hartley operation. He said there had been forty-seven cases collected up to date, with only two deaths. One of the patients died shortly after the operation from shock. The other death was presumably due to the advanced age of the patient.

DR. JOSEPH B. BACON, of Chicago, contributed an interesting paper on

Dermoid Cysts as a Cause of Fistula in Ano.—

All of the cases were of blind internal fistulæ that were sent to his clinic for operation, the fistula being connected with small cysts. The patients attributed their ailment to chronic diarrhœa, ulcer of the bowel, or piles, and could give only an indefinite history of repeated attacks of pain.

The first case was that of a practitioner of medicine who came to the Post-Graduate Hospital, November, 1895, to be treated for painful ulcer of the anus. He was a well-developed, muscular man; weight, one hundred and eighty pounds. He gave an indefinite history of painful defecation, spasm of sphincter muscles, and discharge of pus from bowel, that extended back over a period of several years. After patient was anæsthetized and the sphincters divulsed, an anal ulcer with every appearance of an ordinary mechanical tear of the mucous membrane was noticed on the posterior median line of the anal canal between the internal and external sphincters. The ulcer was covered by old granulations. After removing the granulation tissue with a curette, a fistulous tract was found leading into a small sac, filled with granulation tissue, pus, and a bunch of fine blond hair. The sac was found to lie behind the anus and very near the skin. The external sphincter was severed in the posterior median line and the sac laid open and curetted and converted into an open wound. The wound was packed with iodoform gauze and daily irrigated with boric-acid solutions and repacked. The patient made a perfect recovery in three weeks. The author reported three other cases, and stated that he had done so because there was a limited amount of literature upon the subject. The cases were interesting in that they afforded a favorable prognosis in a certain per cent. of fistulæ in ano, a very important point for those interested in life insurance. The very large percentage of fistulas of a tuberculous origin may prevent patients suffering from fistulæ in ano receiving insurance. Yet a more careful consideration of each case and its history would determine that possibly some of them are due to dermoids, and thus all anxiety for the patient's general infection from tuberculosis would be removed from doubt.

Metatarsalgia, with a Report of Three Cases.—

This paper was read by DR. A. E. HALSTEAD, of Chicago. After dealing with the subject in an exhaustive manner, the author concludes:

1. That what is known as metatarsalgia is not in the beginning a distinct pathologic entity, but rather an early symptom of static flat foot. In cases of long-standing irritation of the plantar nerves by pressure from flattening of the transverse metatarsal arch may cause an inflammation of the nerve, or even in some cases the development of a neuro-fibroma.

2. That most of these cases can be permanently cured by following the treatment usually employed in beginning flat foot—*e.g.*, systematic massage, gymnastics, and the use of properly fitted shoes, and in some cases the application of a metallic brace to the sole of the foot.

3. In cases of long standing, where there is well-marked pathologic change in one or more of the

branches of the plantar nerves, resection of the nerve should be performed. The more radical operations, such as resection of the metatarso-phalangeal joint or amputation of the toe, are not indicated.

Cholelithiasis: A Plea for Operative Treatment.

—By DR. E. MAMMER, of Bloomington.

All cases which are not promptly relieved by the passage of small stones, or by therapeutic measures effectively and judiciously employed, at once furnish true indications for resort to cholecystenterostomy. The operation can be safely done and will be successful when calculi are in the gall bladder only; when they are in the gall bladder and in the cystic duct; and when they are in the ductus communis choledochus, and can be removed, or when, even if left there, the bile will find a free passage by the new channel.

Indications for operation in such as the above may be determined by carefully weighing all symptoms and a thorough study of them in all their relations.

The author reported two cases in which he had operated successfully.

Vaginal Section for the Cure of Retroversion of the Uterus was the title of a paper read by DR. HENRY T. BYFORD, of Chicago, in which the author described the technique of the method which he had employed as follows: The vulva and vagina are thoroughly scrubbed with softsoap, then with strong alcohol and with a 1 to 2,000 solution of bichloride of mercury. The uterus is dilated and curetted, and disinfected with mild or strong solutions, according to the requirements of the case. This preparation is necessary to prevent the infection of the connective tissue and buried ligatures.

A transverse incision, a trifle over an inch long, is made in the vaginal wall just in front of the cervix and the bladder separated from the uterus by the finger as far up as the peritoneal reflection. Then a longitudinal vaginal incision about two inches long is made in the median line from the neck of the bladder to the middle of the transverse incision. The bladder is separated from the vagina for a short distance on either side of the incision to give room for manipulation. The peritoneum is then torn across between the uterus and bladder, an intraperitoneal pelvic examination is made, adhesions are separated, and such parts are treated or removed as may so require. The bladder peritoneum is then seized by forceps and drawn down by successive grips until that which belongs behind the pubes can be seen. Two chromicized catgut threads are introduced about one inch apart through this portion of the peritoneum and subperitoneal tissue as high as possible. Then the anterior surface of the uterus is grasped with tenaculum forceps and the fundus pulled into the vaginal wound and attached to the bladder by means of the above-mentioned catgut threads. The finger is now hooked over the left round ligament, which lies beside the vaginal wound; a loop of the ligament is drawn into sight, grasped by forceps, and pulled down until the inguinal end is taut. A catgut suture is put through it as far from the uterine end as possible and is made to attach it to the uterus just above the normal uterine insertion, which is easily exposed to view by the vaginal retractors. The same is done to the right ligament. The entire vaginal wound is closed with transverse sutures that reunite the bladder to the vagina and also draw the ends of the transverse incision together, leaving one row of sutures in the median line. A few inches of a narrow strip of gauze is placed in the connective tissue in front of the cervix, to be removed in twenty-four hours by pulling on the end, which projects between the sutures into the vagina.

Dr. Byford has operated upon ten patients in this manner, and also upon one patient in whom he merely sutured the fundus over the bladder. In each case the

uterus has remained in a normal, mobile position, without the aid of a pessary at any time. The comfort is greater and the complaint much less than after Alexander's operation. The uterus has no abnormal attachments except the two points of peritoneal adhesions to the bladder, and there can be nothing to fear from subsequent pregnancy.

Iodoform Injection Treatment of Hip-Joint Disease.—By DR. A. H. FERGUSON, of Chicago. The intra-articular medication of tuberculous joints is of recent date and is not yet very widely employed. The author had selected the hip-joint on account of the frequency with which it is diseased, and because he had found it more amenable to the iodoform emulsion injections than any other joint. Objections to the hitherto recognized methods of the treatment of hip-joint disease were mentioned, after which the author outlined the manner of using these injections. He has treated upward of twenty-five cases with the most satisfactory results.

What Measures Best Restrict the Spread of Tuberculosis?—By DR. E. W. ZOOK, of Peoria. The restriction of the spread of tuberculosis, while not a new subject, was one that has not been given the attention it deserves. The author believes that the time is not far distant when a specific cure for tuberculosis will be discovered, but until that time comes we will have to rely upon preventive measures, and if these can be uniformly enforced he thinks we will without doubt be able to check the spread of this disease, but in order to do so we will have to put forth our best efforts.

Permanent Ambulatory Extension in Surgery.—By DR. ALEX. C. WIENER, of Chicago. He said that in fractures of the shaft of the tibia or femur absolute immobilization of the bones in the normal position, either by compression bandages or by weight extension, is indispensable, but is it absolutely necessary to have the patient rest in bed all the long weeks until consolidation is perfect? The speaker replied in the negative. The surgeon gives his patient a dressing tightly fitting the outlines of the extremities, so as to keep the fractured bone in a correct position and to regulate the impaired circulation so that the injured can put his legs on the floor without pain. In order to allow the patient free mobility he is supplied with an apparatus which Dr. Wiener described, and which seems to be very practical and useful in the treatment of the cases under consideration.

Functional Indigestion, Its Causes and Treatment.—DR. J. M. G. CARTER, of Waukegan, in a paper on this subject stated that the term indigestion referred to a condition, not a disease. This disturbance, then, was always functional. The following indications may be regarded as pointing out the course of correct treatment in the class of cases considered in the paper, to be varied to meet the necessities of individual patients: (1) Remove the cause; (2) check or prevent the growth of bacteria; (3) assist digestion, and (4) repair damages done. These indications were then dwelt upon at length.

The treatment requires, first, the removal of the cause; second, the checking or prevention of the growth of bacteria; third, an effort to assist digestion, and, fourth, the repair of damages to the stomach or to the general system.

DR. FENTON B. TURCK, of Chicago, made some remarks upon the pathology of gastritis and demonstrated his method of treating this affection on a patient. He went over substantially the same ground as that covered in his previous contributions to medical literature on this subject, and with which most of the members of the profession are doubtless more or less familiar.

The Differential Diagnosis of Neurasthenia and

Its Treatment.—DR. E. S. PETTYJOHN, of Alma, Mich., read this paper, in which he said that ever since Beard used the term neurasthenia, and Van Dusen directed attention to a group of symptoms so named, the profession has been struggling to map out a definite set of symptoms to be thus classified, and in his opinion we had as yet but poorly succeeded. Althaus, of London, protests against the term, and Gowers says that nervousness covers the conditions. There is one thing upon which authors are agreed, namely, that this group of symptoms indicates disease of some part, or every part, of the nervous system; that there is a marked defect in the nutrition of the cerebro-spinal axis, giving an almost endless variety of symptoms difficult to classify. The changes noted in the patient come on gradually. These changes were described, and also those which occur in cases of neurasthenia. The author believes that neurasthenia as a distinct disease does not exist. Under the head of treatment the author expatiated upon elimination, food, and environment.

Cryptogenetic Sepsis.—DR. JAMES T. WHITTAKER, of Cincinnati, O., said that the terms pyæmia, septicæmia, sepsis, septic pyæmia, are variously employed by different authors. There is no longer support for the different terms. Pyæmia was the term first employed. It was a useful term because it expressed a poisoning of the blood by pus and connected this poisoning with a pus centre. So distinct was this connection that the people understood it by the common term "blood poisoning." But the mere presence of pus in the blood does not necessarily produce blood poisoning. In one sense there is always pus in the blood; that is, there are white blood corpuscles, leucocytes, and these corpuscles accumulate in leucocytosis to constitute a protective process. Pyæmia is now generally understood to mean infection of the blood as indicated by multiple metastases, in the absence of any central depot of suppuration; whereas, septicæmia is used to express the infection of the blood in which there is a decided depot in the absence of demonstrable metastases. It is believed at the present day that rheumatism is caused by micro-organisms closely allied to if not identical with the micro-organisms of pus.

Dr. Whittaker made the point that many of the lighter forms of disease, which had been vaguely described as rheumatism, malaria, incipient tuberculosis, la grippe, or a bad cold were cases of light infection with septic matter in which the micro-organisms of sepsis may be found in the blood, and that individuals who are the frequent subjects of these diseases are carrying about in them manifest or more especially concealed depots or colonies of septic micro-organisms.

The treatment may be dismissed in a few words. The prophylaxis depends upon an increase in the general habits of cleanliness, the greater frequency of ablutions, and more care for higher sanitation.

Officers Elected.—The following officers were elected for the ensuing year: *President*, Dr. A. C. Corr, Carlinville; *Vice-Presidents*, Dr. J. M. G. Carter, Waukegan, and Dr. T. J. Pitner, Jacksonville; *Treasurer*, Dr. George N. Kreider, Springfield; *Permanent Secretary*, Dr. John B. Hamilton, Chicago.

The next meeting will be held at East St. Louis, third Tuesday in May, 1897.

Gonorrhœa.—Dr. Schwimmer used alumnol in injections, irrigation, and instillations (0.5 to 5 per cent.). Its effect in chronic cases seemed to be better than in acute cases. In women tampons soaked in the solution are used more or less successfully.—*Arch. f. Dermat.*, No. 29.

Surgical Suggestions.

Intrathoracic Tumors.—1. The most frequent intrathoracic tumor is sarcoma. 2. The most frequent point of origin is the anterior mediastinum, and in particular the remnant of the thymus gland. 3. Clinically these growths may be grouped as those affecting the anterior mediastinum in which physical signs are prominent, those of the middle and posterior mediastinum in which the symptoms predominate over the physical signs, and those beginning in the pleura in which both symptoms and physical signs predominate from the first.—PEPPER AND STENGEL.

Persistence of Pigmentation in Epidermic Grafts.—Drs. Carnot and Deflandre report to the Société de Biologie, February 15, 1896, that a pigmented graft transplanted upon a white skin in the Gilbert Laboratory preserved its color and extended rapidly at the expense of the latter. In one case the central part became more and more pigmented and the periphery presented a zone of extension equalling about a millimetre, the color of which was intermediary. If a white graft is transplanted upon a black epidermis, it fails to take or disappears quickly, as though the pigmented cells attacked the unpigmented ones and replaced them. The secondary epidermic products undergo analogous transformations—the hairs which grow upon the black graft are first mostly white, but become black as the graft gets older. The epidermic pigmentation of mammifera would then seem to be a cellular property largely independent of vascular and nervous influence. This behavior of epidermic grafts is contrary to that which has hitherto been taught to prevail in man.

Hemorrhoids.—Dr. J. N. Baughman (*American Practitioner and News*) recommends the following:

℞ Fl. ext. belladonna..... ʒ i.
 Fl. ext. horsechestnut..... ʒ ij.
 Tannic acid..... gr. x.
 Vaseline..... ʒ ij.
 M. et fiat ungt. S. Apply to inflamed parts two or three times in twenty-four hours.

Dr. Schmey recommends (*International Journal of Surgery*) painting the nodules once daily with a two-per-cent. solution of nitrate of silver, which causes a reduction in size without pain. In a large number of cases the tumors entirely disappeared in the course of one or two weeks. When patients positively refuse operative treatment this new procedure may prove useful.

Epididymitis.—Dr. J. William White, in the *Medical World*, gives the following formula:

℞ Sodii bromidi,
 Acidi borici..... āā ʒ viij.
 Tr. aconiti..... gtt. viij.
 Tr. belladonnae..... ʒ i.
 Liq. cit. potassii..... q.s. ad ʒ viij.
 M. S. Tablespoonful three times a day.

Put the patient to bed with the scrotum elevated and a pillow under the hips.

Chronic Pyelitis.—Dr. Robin prescribes the following (*Le Progrès Médical*) when pain is present:

℞ Venice turpentine,
 Powdered camphor..... āā ʒ iss.
 Extract of opium..... gr. v.
 Extract of aconite root..... gr. iij.
 Make into twenty pills. Take one every eight hours together with a small glassful of uva ursi sweetened.

Abscess of the Liver.—Dr. Fontan, of Toulon (*Le Progrès Médical*), adopts as rules for operating: (1)

A free incision eight or ten centimetres long as soon as the abscess is recognized; (2) the final resection of one or more costal cartilages to expose the abscess freely; (3) the separate suturing of the peritoneum and of the pleura to prevent the penetration of pus into these serous cavities; (4) complete curetting of the cavity of the abscess, as this method removes the diseased tissue and does not predispose to hemorrhage. M. Fontan reports eighty-six per cent. of cures due to the operative technique and curetting. The best statistics of incision or excision by the bistoury alone give only thirty-six to fifty-one per cent. of cures.

Ulcers of the Leg are usually caused by a depraved state of the local blood supply. The tortuosity of the superficial and sometimes of the deep veins of the leg favors venous stasis and interferes with the nutritive forces of their localities. In order to effect a cure, this condition must be rectified by relieving the veins of their superabundance of blood and by aiding the overdistended venous coats to resume their normal proportions. This is done by bandaging. To be effective, the bandage should be carefully applied, so that equal pressure is brought to bear throughout. The bandage should reach from the toes to the knee.—DR. EDLÉN, *N. Y. Med. Jour.*, March 14, 1896.

Hemorrhoids.—

℞ Gallic acid..... gr. x.
 Extract of opium..... gr. iv.
 Extract of belladonna..... gr. v.
 Simple ointment..... ʒ ss.
 M. S. Apply locally morning and night.

—HARE.

Alopecia.—Dr. Samter, of Königsberg, reports good results from the use of a ten-per-cent. chrysarobin ointment, whereas after using the faradic current for weeks no results seem to have been achieved. Prophylactically, strict antiseptic rules should be carried out in barber shops.

A Novel Tractor.—In the *Rev. de Thér.*, November, 1895, a physician describes the use of a stout cord as an aid to traction in obstetrics. The patient is placed in the usual position and the forceps adjusted. The physician seats himself on a low chair in front. A loop on one end of the cord, which should be about a metre and a half in length and quite thick, is fastened to the left handle of the forceps, then carried across to the right handle and back again several times, making a figure of eight. It is then passed from left to right around the physician's back and fastened to the right handle. In this way the physician can control the forceps with his body and he has free use of his hands. In careless hands this device might do damage, but properly used it is a great advantage.

Leucorrhœa.—

℞ Acidi tannici..... ʒ ij.
 Alcohol. pur.,
 Creosoti..... āā ʒ ss.
 Aquæ dest..... ʒ viij.

M. S. Add a tablespoonful to a quart of warm water and use three or four times a day as a vaginal injection.

—LIROLA, *Progrès Médical*, No. 6, 1896.

Syphilis.—The Société de Dermatologie (*Progrès Médical*, February 8th) has been considering the question of mercurial injections. The conclusions seem to be that their use should not be limited to severe cases, but that they are beneficial in all, and that injection is the best means of administering mercury, on account of its reliability, rapidity, and the intensity of its action. Le Pileur has treated six hundred cases with injections of gray oil, which he especially recommends. Hallopeau and others prefer injections of calomel.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

DEATHS OF TWO VETERANS, SIR RUSSELL REYNOLDS AND SIR GEORGE JOHNSON—MEETING OF MEDICAL COUNCIL—A NURSING EXHIBITION—MEDICO-CHIRURGICAL SOCIETY—REHABILITATION OF GUAIAECUM—GENERAL MEDICAL COUNCIL'S SESSION—THE EXAMINATION SYSTEM—DUBLIN APOTHECARIES' HALL—PENAL CASES—MIDWIFERY INSTRUCTION—GUY'S HOSPITAL—PRINCE OF WALES AND HOSPITALS—ROYAL SOCIETY.

LONDON, June 5, 1896.

WHEN I was writing my last week's letter Sir Russell Reynolds still lingered in the hopeless condition to which my previous statement pointed. Though not appreciably different in the morning, he died the same afternoon, too late to add to my letter the sad but not unexpected news. His health had declined for more than a year. Last summer he was a good deal exhausted by the work entailed on him as president of the British Medical Association. Early in January serious illness was manifested in a sudden attack as he rose from the table at a dinner he had given to his colleagues at the College of Physicians. A little later he went to Hastings for a time, but did not gain strength. On March 23d, on returning from a drive, he slipped on his doorstep and sprained his ankle. He was taken to his bed, which from that time he did not leave, as pneumonia supervened. He survived the immediate attack, but the remainder of his life may be said to have been a gradual failure of strength.

John Russell Reynolds was born in 1828. His father was the Rev. John Reynolds. His grandfather was a physician and F.R.S. His brother, the Rev. H. Reynolds, D.D., principal of Cheshunt College, a learned and greatly esteemed theologian, survives him. The career of the late president of the College of Physicians has been all along successful. He graduated at the London University, carrying off gold medals and the distinction of "university medical scholar." He passed through the various stages at University College, to which he eventually became professor of medicine and physician to the hospital—positions he occupied for many years, where his teaching was most highly appreciated. His contributions to medical literature began with his essay on "Vertigo" in 1854, and his other writings on "Neurology" are very well known. He edited a "System of Medicine," by various writers, extending to five volumes, 1866-79. Up to the latter date this work is full and reliable, but so great has been the progress of medicine since that the "Twentieth Century" will probably push it aside as largely obsolete. His work on neurology was greatly appreciated abroad as well as at home. Several of his writings were translated into foreign languages and many learned societies delighted to enroll him among their members. He was elected a fellow of the Royal Society, served in most of the offices at the College of Physicians, becoming president in 1893, after which he was created a baronet, having been physician to the Queen's household from 1878. He has died honored of all his brethren for his sterling character and genuine worth, and a large number of the leaders of the profession were present at the funeral service on Tuesday (2d inst).

Another veteran has also fallen. Sir George Johnson, F.R.S., whose name will be familiar to your readers, died on Wednesday afternoon (June 3d), after a brief illness. He was in his usual health and spirits until Monday, when, on returning from a drive, he was

seized with hemiplegia. He regained consciousness, but gradually sank. He was in the seventy-eighth year of his age, and occupied a considerable position in the profession throughout a long and honorable career. For many years he was physician to Kings College Hospital and professor of clinical medicine, and on retiring was made consulting physician and emeritus professor. You will remember his views on cholera, which at one time excited much controversy. Only a few months ago he issued a volume on the subject, in which he reiterated his views with all his old energy and conviction. His writings on kidney diseases were also well known, and he had just completed a work on the "Pathology of the Contracted Granular Kidney," which narrowly escaped being a posthumous production, for I hear that the publishers only delivered copies on the day before he died. This work cannot fail to interest those who opposed his views of this subject as well as those who accepted them, as it will be his latest utterance, and no doubt many new facts will be weighed and his judgment pronounced in the light of the most recent additions to our knowledge.

Sir George was physician extraordinary to the Queen, a member of the senate of the London University, where he took his M.D. as long ago as 1844. In 1850 he became a fellow of the College of Physicians, where he passed through most of the official positions and became vice-president in 1887. In 1864 he published a couple of lectures he had delivered at the college on the laryngoscope, and he retained to the last a certain interest in laryngeal diseases, and consented to be president of the Second Laryngological Society—though it is hard to see why the specialists could not unite in a single society.

The General Medical Council met on Tuesday, when the three new members took their seats and the president was re-elected and delivered his address. Mr. Teale brought forward a resolution respecting the examinations, which was partly discussed and then referred to the education committee. The case of the Dublin Apothecaries' Hall was taken up the next day, but adjourned over yesterday, which was occupied with questions of professional misconduct. This being so, I, too, will adjourn further notice of the proceedings which are so unfinished.

A nursing exhibition has been open all the week, where various things are shown of more or less use to the sick or injured. Music, the new photography, and other attractions have been provided to induce those to come who are not sufficiently interested in nursing.

Many prescribers value guaiacum and serpentary so little that they would not object to see them expunged from the pharmacopœia. Sir Alfred Garrod believes in the virtues of both, especially guaiacum. Accordingly, he undertook its rehabilitation at the last meeting of the Medical and Chirurgical Society, in which somewhat skeptical atmosphere he claimed to have been successful in establishing the following points: (1) Guaiacum was innocuous and might be taken for an indefinite period of time, and looked upon as a condiment rather than as a drug, was as harmless as ginger or any other condiment. (2) Guaiacum possessed a considerable power, but less than colchicum, in directly relieving patients suffering from gouty inflammation of any part; it might be given whenever there was but little fever. (3) Guaiacum taken in the intervals of gouty attacks had a considerable power of averting their recurrence: in fact, it was a very powerful prophylactic. (4) Guaiacum did not appear to lose its prophylactic power by long-continued use. (5) There were a few persons who could not readily continue the use of guaiacum; for such cases there were other drugs whose action was in some respects similar, and perhaps serpentary was one of the most powerful of these. He had given it successfully in

gouty inflammation in the elderly subject, and as a prophylactic doubted not that it was possessed of considerable power. As to the origin of uric acid in the animal economy, instead of supposing that it was formed in the system by the metabolism of the nitrogenized tissues and then thrown out by the kidneys, he was of opinion that it was produced from urea and other nitrogenized bodies in the blood by the direct action of the kidney, and that when uric acid was contained in the blood this arose from the absorption from the kidney structures of the urate of ammonium, depending on the want of sufficient throwing-off powers in these tissues. He did not think that guaiacum affected the formation of uric acid, but that it acted directly on the kidney itself as a stimulant and enabled it to get rid of any accumulation in the tubules, and thus prevented absorption from them into the blood. In confirmation of this view, patients when taking guaiacum often had unusual deposits of urates in their urine.

Dr. Norman Moore had seen at least one hundred instances post-mortem of persons displaying the features in morbid anatomy which Sir Alfred B. Garrod had first shown to belong to this disease. Colchicum might be given for long periods with advantage and some success in warding off the attacks.

Dr. Murrell said that he could support Sir A. B. Garrod's conclusions as to the efficacy of guaiacum in chronic gout. He had used it during the last six years, not only for chronic gout, but for rheumatism, tonsillitis, and chronic bronchitis associated with the gouty taint. He favored a confection.

Dr. Haig agreed that guaiacum tended to ward off gouty manifestations, but could not accept the explanation offered as to the way in which the drug acted. Iodide of potassium provoked diuresis and dilatation of all the blood-vessels, with a fall of blood pressure. Lithia and ammonia had a similar action, as also had copaiba, tar, cannabis indica, certain salts of calcium, and certain bitters, such as chiretta, gentian, and possibly serpentary. Copaiba contained a large quantity of acid, and guaiacum agreed with it in this. He believed that all these drugs diminished the excretion of uric acid and kept the blood clear of it, and he had explained fully elsewhere the method of action of some of those drugs. He accepted the view that urate of ammonia was not formed from urea in the kidneys, but that the reverse took place. Much of the uric acid met with in disease was not formed in the system, but was introduced with animal food.

Dr. Ewart thought that the action of guaiacum upon the capillaries was not limited to the kidney, but extended to the whole system, and in particular to the capillaries of the muscles; indeed, the effect of guaiacum in relieving painful manifestations located in the muscles was well known. It was easy to imagine that any interference, however small, with the metabolism of the muscles must have an appreciable effect upon the juices, and as to the glandular system guaiacum acted in that way also, and was a recognized hepatic stimulant. If the drug were used over a long period in doses sufficient to cause a laxative action, this would influence gouty persons materially. He found tincture of iodine very useful in combination with guaiacum.

The president, Dr. Dickinson, said that in rheumatism guaiacum had been used at St. George's Hospital for at least a century, and was certainly much more successful than other remedies in use at the early part of that time. The treatment of acute rheumatism by guaiacum had been continued until twenty years ago, and even now it was used for chronic rheumatism. From his own experience he could speak very strongly as to its value in some forms of acute rheumatism as well as in gout. With regard to the relation of uric acid to gout, he placed himself in the position

of a disbeliever. There was no doubt of its presence, but he preserved doubts as to its being the real cause. Was it not what we might call a by-product? During convalescence from scarlet fever, when nephritis was present, it was not uncommon to find enormous quantities of uric acid passed, but that did not necessarily lead to gout.

Sir A. B. Garrod, in reply, said that one never missed finding urate of sodium deposited in the tissues after the slightest attack of gouty inflammation. He admitted the value of guaiacum in acute rheumatism, but many cases formerly treated as acute rheumatism were really instances of acute gout. He was convinced, also, that guaiacum would relieve muscular pains which were not gouty. Further, there could be no gouty symptom without the presence of urate of sodium in the blood, and this had no relation to the amount thrown out by the kidneys. Guaiacum might act by increasing the amount excreted, causing visible deposit, to which the patient would call attention.

LONDON, June 12, 1896.

THE most important subject discussed in the session of the General Medical Council which concluded on Tuesday was that brought forward by Mr. Teale in a resolution which is a very serious indictment of our examination system. The subject has for some time been forced on teachers by a very unpleasant experience, while students have groaned under the continually increasing demands upon them. Examinations have been multiplied and the ratio of rejections has increased at every step, so that Mr. Teale calculated that if every student took his share of plucks he would be rejected twice in his career. Of course, such averages are mere indications, and if not used carefully may mislead; but there is yet a more serious aspect of this question, viz., the continuous rise in the percentage of plucks. The more we multiply examinations the more fatal does each become, so that there is obviously good reason for the alarm that has been raised. Mr. Teale regarded the examinations as faulty on account of the element of chance which is almost inseparable from them, and also from avoidable circumstances, viz., the hurry with which some of them are conducted and the absurd questions which are too often set. This latter point he illustrated by a series of examples of the misguided energy of examiners.

The council is undoubtedly responsible for the manner of regulating the examinations which has resulted in a bitter cry from teachers and students, and it should lead to much searching of hearts by councillors and examiners. These last must be subjected to control. Every examiner exalts his own subject until the only plan of meeting his requirements is systematic cramming, to the neglect of clinical work. Thus we have sent up for examination men who can give parrot replies to questions framed from certain text-books, but who are at a loss as to how to put their knowledge to use by the bedside. Facts and rules are insisted on and are therefore accumulated by rote, while the more important part of true training is rendered impossible of attainment.

Mr. Teale would maintain the standard on subjects which it is essential for a practitioner to know and "retain the knowledge of," but would withdraw from public examinations those subjects which he should "know about," and let the schools teach and certify them. There is certainly some danger if this suggestion were adopted that the competition of the schools, which is too keen now, might lead to the perfunctory certification in these subjects of all who had attended the lectures, or, which is almost the same, paid the fees. Surely the qualifying body should not be relieved of its responsibility. Let us set up no school

examinations to worry the students more, but insist that the teaching is sufficient for a young man of average intelligence and increase the preliminary education so as to ensure the fitness of every student to enter on the curriculum prepared for his work.

The council, "without committing itself in any way to the views" brought forward, referred the matter to the education committee for consideration and report.

The Dublin Apothecaries' Hall made the proposal suggested by the privy council for the appointment of examiners by the medical council. This was discussed with the same acrimony that has marked the effort to shut up the hall in the interest of the Irish College of Physicians. No doubt the hall is useless. We have too many licensing bodies, and this ought not to have been one. But, having attained a legal status and being unwilling to commit the "happy despatch," the effort to get rid of it by a side-wind is mean. If the council is satisfied that its examinations deserve such condemnation, the acts provide a method of terminating its career in a straightforward manner. Eventually the council deferred any expression of opinion and directed communications to be made to the hall and to the College of Surgeons, with a view of bringing about a conjoint board. No doubt the hall will be ready enough to unite again; but will the college?

Three days were devoted to penal cases. Three names were ordered to be removed from the register for infamous conduct, of which the council, having heard the defence and deliberated *in camera*, found them guilty. Another case terminated in the announcement that the charge was not proved. A dental offender was found guilty and judgment postponed.

The council is a very expensive court for the trial of these cases. Moreover, its proceedings are often destitute of all appearance of judicial dignity. It is to be hoped some more appropriate tribunal may be entrusted with the trial of these cases. A body appointed by the council might, perhaps, be authorized by the next medical act. Lawyers make short work with any black sheep that gets into their ranks. Why should not doctors be provided with an equally efficient method?

The council resolved that in future the alternative of three months' attendance on the indoor practice of a lying-in hospital should be attendance on twenty labors, of which not less than five should be conducted throughout (including the whole puerperium), under the direct supervision of a registered practitioner.

A statement by Mr. Muir Mackenzie, as standing counsel, was made to the effect that he is not satisfied that it is necessary or advisable to seek to amend the penal clause of the act.

On Wednesday the Prince of Wales again raised his voice on behalf of hospitals—a cause he has often pleaded before. This time it was for Guy's Hospital, the income of which has been so reduced by the fall in the value of land that the governors are compelled to appeal to the public. The endowment provided by Thomas Guy for the maintenance of this hospital was, in accordance with his will, entirely invested in land. The rents proved sufficient until some fifteen years ago, when the depression began to be seriously felt. When all economies failed, even the closing of wards, £100,000 was raised by subscription to tide over what was hoped was only a temporary difficulty. But the fall in prices has increased until now, and an effort is being made to raise a fund to bring in £15,000 a year. To help toward this, a festival dinner and reception was arranged to be held at the Imperial Institute. It came off on Wednesday, when the prince presided with his usual grace and geniality, pleaded the cause of the hospital in a powerful speech, and accepted the office of president. The response was unprecedented, and

this festival will be memorable for the amount announced at it—a total of £167,528.

Of course, a great proportion of this sum had previously been sent forward or promised, but the amounts subscribed in the course of the festival were worthy of the occasion. The reception after dinner was attended by a great throng of fashionable society—so great that, as the weather was wet and the gardens accordingly deserted, there was quite a crush in some parts of the spacious buildings, especially about the staircases and some of more contracted parts. Still, on the whole, the thousands of ladies and gentlemen present met with very little inconvenience, and seemed thoroughly to enjoy the great reception, which did not disperse till long after midnight.

The previous day (Tuesday) the prince had accompanied his wife to Hackney, where Her Royal Highness opened a bazaar on behalf of the Band of Hope. On this occasion the prince expressed for himself and the Princess the pleasure it gave them to assist in this good work, and declared they had been delighted with their reception along the route and in the hall. Having gone round the stalls and made purchases, the royal visitors were entertained with a gymnastic performance by some of the children, and left amid loud plaudits, which were redoubled outside all along the route.

On Monday the prince attended a meeting of the council of the Hospital Sunday Fund, of which he is a vice-president. There he presented to Mr. Burdett an album containing the portraits of the council, and which, with an address they had voted him, was offered in commemoration of his successful efforts in increasing the fund. Mr. Burdett was naturally gratified that the prince should have come on this occasion.

With all this, I may safely say the prince has done some good work this week and emphasized his well-known interest in all efforts on behalf of the sick poor.

The Royal Society's *conversazione*—the "ladies' night," as it is familiarly called—was held on Wednesday and well attended, notwithstanding the counter-attraction mentioned above. The "X" rays and other exhibits were as attractive as usual.

Dr. Thomas Barlow has been appointed, in succession to the late Sir R. Reynolds, physician-in-ordinary to Her Majesty's household.

FOREIGN PRACTITIONERS IN FRANCE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In my number of your journal just received (May 9, 1896, p. 684) you refer to the "Rampant Protectionism for French Physicians," and the question is asked, "How many of the interlopers are American?"

Thinking this would interest your readers, I venture to give some details of the question.

All the French medical journals are full of what they call the invasion of the foreigners (doctors who come to France to practise medicine). This, although these foreigners are made to pass all the medical examinations that Frenchmen pass.

A late writer says: "These people come here to take advantage of the foolish public, who are attracted by anything that comes from afar off and that has a barbarous name. Most of these stranger doctors are Russians and Jews, who fly from their native soil to divide our bread with them, as they are tired of black bread."

Two new articles are proposed to the medical laws: 1st. All foreigners can enter the French faculties of medicine, but the diploma given will not entitle them to practise in France.

2d. No foreigner can practise medicine in France unless he has been naturalized French, has done his

military service, and has passed the examinations for *bachelier*, like Master of Arts.

It is therefore evident that great difficulties will be put in the way of any foreigner who wants to practise in France.

Up to the present the foreign Master of Arts degrees or similar ones have been accepted as sufficient for entrance in French faculties, and some allowance off has been made to holders of good medical diplomas.

In late years, however, foreign medical men have barely been allowed to enter the French schools and have been compelled to pass all the examinations (eleven in all). The medical examinations are called five, but are each divided in two, making ten, which, with the printed thesis examination, make eleven examinations in all.

The writer came in under this last ruling.

The "invasion" is mostly a Russian one and is the fault of the French themselves. In late years they have encouraged and shouted for everything Russian. Any student of a Russian school was admitted to the Paris faculties (males and females). This has led to the present overwhelming of the French doctors.

The Russians are poor men and women who do not care to return to their own inhospitable land, and stay to practise in France and with and upon French people. They speak excellent French as well as very often English and German, and practise among the French as well as the English or any others.

It is a very different matter with the English-speaking (English and American) doctors who practise in France. The better-class English and Americans travel much in France and pass seasons in its winter and summer health resorts, and they demand a physician of their own country and language when ill.

This has caused a certain number of English and American doctors to settle in France, and they practise only with their own country people, never accepting a French patient.

They have all had to pass the full examinations of the French faculty the same as the French students, and have as well a diploma from their own medical schools, thus having had a double education.

As the question is asked, perhaps it would be well for you to give the full list of all the American physicians now practising in France, as follows:

Aix-les-Bains: Dr. Thomas Linn (in summer).

Nice: Dr. Thomas Linn (in winter).

Paris: Drs. Austin, A. Clarke, B. F. Dearing, Pike, R. R. Good, G. Halsted-Boyland, Chamberlain, M. F. Hein, Magnin, Reiss, Mrs. Klumpe-Dejérine (wife of Professor Dejérine), Whitman.

Thus, twelve are in Paris, and one, Dr. Linn, at Nice and Aix-les-Bains and the rest of France.

The English doctors are about twelve also in Paris, eight in Nice, six in Cannes, five in Monte Carlo, six in Mentone, one in Beaulieu, and two in Hyères.

There are about, then, a dozen Americans in all France, and some twenty-eight English in south France and twelve in Paris; thus, forty of the latter in all France.

This surely is not a great "invasion" when the thousands of English and American invalids are considered.

The French doctors need to be told that the only competition they have is from the Russians, whom they have brought to France themselves, while, so far as the American and English doctors are concerned, they never practise among the French, and it is because they reside there that many English and American invalids make a stay in French resorts. AMERICUS.

Quinine is distinctly contraindicated in inflammation of the middle ear, of the skin, meninges, and the urinary and alimentary tracts.

Typhoid fever.....	7	1
Scarlet fever.....	66	5
Cerebro-spinal meningitis.....	0	4
Measles.....	178	15
Diphtheria.....	219	40
Small-pox.....	0	0

Mosquitoes and Malaria.—Dr. Manson believes that malaria may be and often is propagated through the agency of the mosquito. We quote his views from *The Lancet* of March 21, 1896, as follows: "I think I have advanced many cogent reasons for believing that the plasmodium malarie on leaving man, and as a normal step in its life history, becomes parasitic in the mosquito, and that in this insect it enters some cell—as any gregarine or coccidium would do—and probably develops into its reproductive sporulating form just as it does in the blood corpuscles of man. What then? How can its spores get out of the mosquito so as to increase and multiply and preserve its species from extinction when in the course of nature the mosquito dies? How, too, does it spread over the land, and how does it get back to man again? Before attempting to answer these questions, I must first describe very briefly a passage in the life of the mosquito. The female mosquito, after she has filled herself with blood—the male insect is not a bloodsucker—seeks out some dark and sheltered spot near stagnant water. At the end of about six days she quits her shelter, and, alighting on the surface of the water, deposits her eggs thereon. She then dies, and as a rule falls into the water beside her eggs. The eggs float about for a time and then in due course each gives birth to a tiny swimming larva. These larvæ, in virtue of a voracious appetite, grow apace, casting their skins several times to admit of growth. Later they pass into the nymph stage, during which, after a time, they float on the surface of the water. Finally, the shell of the nymph cracks along its dorsal surface and a young mosquito emerges. Standing, as on a raft, on the empty pelt the young mosquito floats on the surface of the water while its wings are drying and acquiring rigidity. When this is complete it flies away. The young mosquito larvæ, to satisfy their prodigious appetites, devour everything eatable they come across; and one of the first things they eat if they get the chance is the dead body of their parent, now soft and sodden from decomposition and long immersion. They even devour their own cast-off skins. In examining mosquito larvæ one often comes across specimens whose alimentary canals are stuffed with the scales, fragments of limbs, and other remains of the parental insect. As we have seen that the mosquito larva devours its own and its neighbor's exuviae, we can readily understand how, once gregarines have been introduced into a pool of water, the larval mosquitoes in that particular pool become infected by the parasite. But as the mature mosquito when she quits her nymph husk also contains numerous gregarines, we can also understand how she, too, carries the infection with her, scattering it about the country in her fæces or conveying it to any other pool where she may lay her eggs and afterward die. Her body is

then devoured by her progeny or by any other mosquito larvæ that already chance to be in the pool. Along with her body, of course, the larvæ swallow any gregarine germs it may contain if they have not already been picked up by the larvæ when feeding on the mud at the bottom of the pool. Does not this little story of the gregarine indicate the way, or a way, in which that other mosquito sporozoon—the plasmodium malariae—multiplies? Does it not indicate how this parasite, in which man is so much interested, passes from mosquito to larva, from larva to mosquito, in never-ending series? Does it not indicate how the plasmodium disease of mosquitoes spreads from pool to pool and is scattered broadcast about the country, and does it not indicate how it may get back to man again? We can readily understand how the mosquito-bred plasmodium may be swallowed by man in water, as so many disease germs are, and we can readily understand how it may be inhaled in dust. Mosquito-haunted pools dry up. The plasmodia in the larvæ and those that have been scattered about in the water, finding themselves stranded by the drought and so placed in a condition unfavorable for development, pass into a resting stage, just as they do when by quinine or other means man is rendered temporarily unsuited for their active life. The dried specimen of the pool, blown about by winds and currents of air, is inhaled by man, and so the plasmodium may find its way back again to the host from whom its ancestors had, perhaps, started generations back. I would conjecture that on entering man and on entering the larval mosquito it develops into a flagellated spore similar to the flagellated spore into which it develops in the mosquito's stomach. In this way it would be enabled to penetrate the mucous surfaces and get into the human blood cell. Many mosquitoes die without getting to water; all male mosquitoes die without seeking water. They may die far from water, blown away, as we know mosquitoes are, by high winds. The bodies of such mosquitoes fall in time on the soil and decompose. The parasites they contained pass into the resting stage, and in this form they also may be carried into the air by currents, or be blown about as dust, or be shaken out by man when he disturbs the soil. In this way the plasmodium may find a route back to man again. In this way, too, we may explain the occurrence of those cases of malaria which apparently, though not really, are unconnected with swamp or stagnant water. Such is my view of the life history of the malaria parasite, and the rôle of the mosquito with regard to it, and of the process by which man becomes infected."

Bacteriology of Air Passages.—In an article read before the Academy of Medicine, April 7th, by Dr. W. H. Thomson, he quotes from Dr. St. Clair Thomson and Dr. R. T. Hewlett, of the Bacteriological Department of the British Institute of Preventive Medicine, to the section on pathology at the last annual meeting of the British Medical Association, which led to special research as to the fate of micro-organisms in inspired air. They calculate that the lowest estimate of organisms inhaled every hour would be fifteen hundred, but in London atmosphere it must be common for fourteen thousand organisms to pass into the nasal cavities during one hour's tranquil breathing. Beginning with the trachea, they found that the mucus derived from the trachea of all animals recently killed in the laboratory was always sterile. The mucous membrane of a healthy nose only exceptionally shows any micro-organisms whatever. The interior of the great majority of normal nasal cavities is perfectly aseptic. The vestibule of the nares, the vibrissæ lining them, and all crusts forming there are generally swarming with bacteria. The vibrissæ seem to act as a filter,

and a large number of microbes meet their fate in the moist meshes of the hair which fringes the vestibule. This arrangement not only arrests the ingress of germs, but by the action of ciliated epithelium those which have penetrated into the nose are rapidly ejected.

Sanatorium Treatment of Phthisis.—Dr. Otis (*New York Medical Journal*, June 3, 1896) writes as follows: "It seems to me that it is to be deplored that the main object of all sanatorium treatment—namely, the hygienic—should in any way be obscured in these laudable attempts to establish special institutions for the treatment of consumption by the more specious claims of special methods of treatment or specifics. It is well to again repeat that up to the present time there has been discovered no specific which will cure consumption, and the best results have been, and are now, obtained by the hygienic, open-air treatment, as illustrated in the best-equipped and best-conducted sanatoriums. The extraordinary and unexpected, like the 'X' rays, may at any time happen in the discovery of the devoutly desired specific or immunizing serum; but when it does come, if ever, there will still be as great a need of sanatoriums as at present, where the damage left in the wake of the dislodged and routed bacillus and his confrères can be repaired, and the battered body gently and skilfully restored for further service."

Fractures of the Cranial Vault.—Dr. Senn says that operative interference is absolutely indicated under the following circumstances: 1. All open fractures, including gunshot and punctured fractures. 2. Depressed fractures attended by well-defined symptoms caused either by the depression or intracranial complications. 3. Rupture of the middle meningeal artery with or without fracture of the skull.

Books Received.

While the MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

A METHOD OF EXAMINING THE PELVIC CONTENTS WHICH RENDERS EXPLORATORY LAPAROTOMY UNNECESSARY IN INFLAMMATORY CONDITIONS OF THE ADNEXA UTERI, AND IN CERTAIN OTHER DISEASED STATES OF THE PELVIC VISCERA.

By W. R. PRYOR, M.D.,

PROFESSOR OF GYNECOLOGY, NEW YORK POLYCLINIC.

UP to two years ago the writer performed abdominal section upon certain patients who presented local and general symptoms strongly resembling pyosalpinx. Upon opening the abdomen, either a hydrosalpinx or broad-ligament cyst, or large cystic ovary, matted by recent lymph to an occluded tube, was found. Meeting such conditions, no method of treating them other than removal appeared safe. Again, other cases were encountered which were very obscure, and in which persistent pelvic pain with tenderness at the sides of the uterus demanded a clearing up of the diagnosis by abdominal section. In other words, we were forced in our fallibility to do a grave operation, in order to make a diagnosis.

The very uncertainty attaching to our diagnoses lead some to shamefully abuse the operation, using as an excuse the necessity for a clear diagnosis, and the words "exploratory laparotomy" became the attractive cloak behind which ignorance worked. The laparotomist, having once gotten in the belly, must have a token of his prowess, and absolutely normal organs were removed. It was in the consciousness, then, of the mistakes inherent in his specialty that the writer sought to develop a method of approaching the adnexa uteri in obscure cases which would be a radical departure from old procedures, and which would both clear up doubtful cases and stay the hand of the laparotomist. This operation will assuredly clearly draw the distinction between those who can and those who cannot do this sort of work. For, while the new operation is simple, yet is the space limited. There is no such gate to throw open as exists between the xiphoid and pubis. In front of the vaginal incision lie the uterus, uterine arteries, ureters, and bladder, behind it lies the rectum, and above are the coils of small intestine. The regional anatomy is intricate but fairly constant. I have this to congratulate myself upon, that experience as an apprentice is demanded to do this operation and a good deal of manual dexterity. Having these, the operation is easily performed, and is devoid of risk. Without them, none should try it.

Operation.—For two days before the operation the vagina is kept filled with a gauze dressing, soaking wet with bichloride solution, 1 to 5,000. At the second renewal of this dressing, twenty-four hours before the operation, the patient is shaved. This wet antiseptic dressing is applied for the purpose of loosening the superficial layers of vaginal epithelium, and it should be ample enough to spread out the vaginal

rugæ. The patient is placed in the lithotomy posture. At the time of operating the external genitalia are scrubbed with a one-per-cent. solution of lysol, followed by Thiersch's solution. The vagina is cleansed with the same solution, using for this purpose the hair brush which jewellers employ to clean watches.

The uterus is curetted, irrigated with a boiled one-per-cent. solution of salt, and its cavity swabbed out with iodoform gauze to remove débris. All instruments employed in this procedure are cast aside and

FIG. 1.—The cul-de-sac incision is made with scissors from *x-x*. Blunt tearing with the fingers is made out to the lateral vaginal walls to *A-A*. The level of the uterine arteries is much above this line of incision, approximately at *u*.

the vagina is again flushed out with Thiersch's solution. With stout, blunt traction forceps the uterus is pulled down, and the point at which the vagina is reflected from the cervix is demonstrated by moving the cervix up and down in the vaginal vault. This point of reflection is shown by a crescentic fold which appears just behind the cervix when the cervix is shoved up.

Picking up this fold in the middle with strong mouse-tooth forceps, the operator cuts through the vaginal mucous membrane at *y* (Fig. 1). This inci-

FIG. 2.—The uterus (*U*) is held up behind the symphysis (*S*) with the bladder (*B*) by the trowel (*A*), while the rectum (*R*) and posterior vaginal wall are pulled down by the retractor (*Y*).

sion is extended to each side to *x-x*, making a cut about an inch long, or a little less, usually, than the diameter of the cervix of a parous woman. The scissors cut through the vaginal mucosa only. The posterior flap is now grasped at its centre by stout forceps, and

while making down-traction upon the uterus and this flap the operator pushes his finger into the cul-de-sac up to the level of the internal os. If the finger has not already perforated the peritoneum, the cavity is wiped dry and the peritoneum picked up with forceps and cut with scissors. A digital examination of the pelvic contents is now made, still keeping up down-traction on the uterus. Having satisfied himself that an ocular inspection is necessary, the operator introduces two fingers into the opening in the cul-de-sac, and, separating them laterally, he tears the vaginal mucous membrane and peritoneum out to the points *A, A* (Fig. 1). Very rarely will the vaginal mucosa be found so stout that he cannot do this. Should it

demonstrated the probable existence of pus foci, to which the intestines are attached, these latter should be separated before putting the table into Trendelenburg's position, in order to prevent escape of pus into the abdominal cavity.

The intestines having been freed in such cases, a complete diaphragm of gauze pads is put between the pus foci and the intestines above, and the Trendelenburg position secured. But in those cases in which the purulent accumulation is extensive enough to cause any degree of adhesions, "exploratory incision" is not often necessary; for the diagnosis is generally sufficiently clear to indicate the proper form of radical operation. It is in the doubtful cases—cases of possible hydrosalpinx,

broad-ligament cyst, or large ovary with adherent inflamed tube, that we find the indication for this, as for the abdominal exploratory incision.

Tubal pregnancy, hydrosalpinx, broad-ligament cyst, ovarian cystoma, occluded tubes, pelvic adhesions, pyosalpinx, uterine fibroid—in fact, all the various lesions of the peritoneal face of the uterus and of its adnexa, I have found and demonstrated by this procedure.

To grasp the ovaries and tubes with Luer's forceps and sever their adhesions is easy.

Cysts of the ovary may be punctured, and so can blood clots in the ovarian stroma. The clear sterile fluid of a hydrosalpinx or broad-ligament cyst can be evacuated. Adhesions between an occluded tube and the ovary can be readily broken. In fact, by this means of exploring the pelvis, we can apply conservative measures to a class of cases which would be

subjected to great risk were conservatism attempted from above.

I have also succeeded in showing that a supposed cancerous involvement of the rectum was nothing but a mass of lymph about a diseased ovary and tube. In five cases I have demonstrated to spectators the vermiform appendix.

Absolutely and without mutilation can we make a positive diagnosis of the pelvic contents from the pelvic brim to the vagina. In a discussion of my operations later on, I will bring out certain other points relating to treatment.

Having satisfactorily examined the pelvis, all fluid is wiped away, the uterus again swabbed out, and now packed full of iodoform gauze. The gauze pads are now removed and a loose plug of iodoform gauze is inserted just within the edges of the vaginal rent; but it must fill the opening to prevent protrusion of small intestine. The uterus and this plug are replaced

FIG. 3.—The cul-de-sac is opened. The posterior vaginal wall is held down by the retractor, while with the trowel the uterus is shoved up against the bladder. The space obtained is estimated by comparing the length of the operator's index finger with the distance between the blades of the retractors. In this case it was $2\frac{1}{4}$ inches.

be so, he will lightly touch it with a scalpel in the direction in which he wishes the tissues to separate. The medium blade of the long Péan retractor is introduced into the pelvic cavity, the forceps on the posterior flap are removed, and the cervix is freed from the traction forceps. The Péan-Pryor trowel is now inserted into the pelvis and the uterus forced up behind the symphysis (Fig. 2). This will widely open up the pelvic cavity. Into this opening a gauze pad, to which is attached a stout string, is inserted to prevent descent of the intestines and to catch any sero-sanguinolent fluid.

The patient, still on the back and with legs bent upon the trunk, is thrown into Trendelenburg's position (Fig. 3). By gentle manipulation with small gauze pads held by Hunter's forceps, the intestines and omentum are made to enter the abdominal cavity. When it is found that the intestines are adherent, they are gently freed. Should the digital examination have

masse, and the vagina is filled with gauze. A self-retaining rubber catheter is inserted into the bladder, and the sphincter ani dilated. No morphine is given. The bowels are moved by salines in twenty-four hours, when light diet is begun. After two days the bladder is irrigated with boric-acid solution and the catheter removed. On the third day the patient is put in Sims' position and the uterine packing removed without irrigation. Whatever vaginal gauze has been taken out to do this is replaced by fresh dressing. I leave the cul-de-sac plug in for from seven to ten days, according to the character of the case. It is removed and replaced under a short chloroform narcosis. In doing this the patient is in Sims' position. The operator

FIG. 4.—1, Péan-Pryor trowel; 2, Péan retractor; 3, Luer's pile forceps; 4, Hunter's sponge holder; 5, Pryor's traction forceps; 6, self-retaining catheter.

must be careful to support the cervix anteriorly with the trowel, so as not to disturb the lymph behind the uterus. A second dressing is made a week later, without pain, and repeated until the opening closes. I let the patient sit up in bed after the first dressing, get out of bed in two weeks, and become an office case between two and three weeks.

These incisions produce no ill results whatever. The lymph which forms behind the cervix is exceedingly evanescent. I would call the attention of the reader to the difference between the amount and character of the lymph which is thrown out about an antiseptic absorbent dressing and that which is the exponent of a pathogenic invasion. Even in cases of puerperal infection subjected to this operation the uterus is entirely movable in two months.

The cul-de-sac closes rapidly, and leaves a scar which is with difficulty found after a few months have passed.

The amount of room which I secure is amply sufficient for purposes of inspection. I enter the cul-de-sac in from one to five minutes. There are two layers anatomically—vaginal mucosa and peritoneum. One small vessel is severed, the azygos artery of the vagina. It is so insignificant that I have always found the few minutes' crushing with the heavy forceps while opening the peritoneum to be sufficient to control it. No nerves of sensation are severed. My incision is made below the line of the broad ligaments and uterine arteries with the accompanying ureters. The blunt tearing of the vagina is made parallel with the branches of the vaginal artery, and they are never wounded. Six instruments are needed for this operation and one assistant.

Roughly described, the distances from the cul-de-sac to the vulva and to the anterior abdominal skin are the same. When I open the cul-de-sac and attempt to separate the blades of my retractors, I find I get but little space unless I throw the woman into Trendelenburg's position. This is because complete relaxation of the pelvic muscles does not occur until they cease to feel the necessity for supporting the intra-abdominal pressure.

Even in an old nullipara with rigid muscles, I get from one and one-half to two and one-half inches be-

tween the blades of my retractors. My belief is that there no longer exists an indication for cœliotomy as an exploratory procedure, or for purposes of treating adhesions, adherent retropositions, occluded tubes, cystic ovaries, hydrosalpinx, or broad-ligament cyst.

The application of the procedure to adherent retropositions has been previously described.¹

Should a vaginal hysterectomy be indicated, the exploratory vaginal incision completes the first step of the radical operation. In case the operator deems it wise to open the abdomen, the vaginal opening made for exploration furnishes the rational drainage space. In other words, where exploration alone is demanded, and in certain cases now subjected to cœliotomy, the vaginal operation above described is a complete procedure; and in other cases in which radical work is indicated my operation is but preliminary to what is to follow.

The Results of the Conservative Vaginal Section and of Vaginal Hysterectomy, in Inflammatory Lesions of the Adnexa Uteri.—In order that operators may see how the above-described method of examining the pelvic contents modifies our work, I will tabulate the last fifty-three cases I have operated upon. The position of the patient in these cases occupies the same important relation to the operation that Trendelenburg's position does to suprapubic ablation of the uterus.

So long as the vaginal operation was the blind, bloody work which we first saw, it scarcely appealed to those of us who were used to the suprapubic operation. But now the operator can see every step of his dissection if he pleases to do so.

FIFTY-THREE CONSECUTIVE CASES OF CONSERVATIVE AND RADICAL OPERATIONS UPON THE ADNEXA UTERI, THROUGH THE VAGINA.

No.	Initials.	Age.	Lesions.	Operation.	Result.
1	R. B.	33	Retroversion with adhesions.	Cul-de-sac opened, uterus released and replaced.	Cured.
2	M. L.	35	do.	do.	do.

The operation of breaking up adhesions through the cul-de-sac and replacing the uterus without suture I have previously described. My persistent use of this operation is due to the fact that I have always succeeded in relieving my patients. After the cul-de-sac closes, I employ such plastic work on the vagina as may be necessary. The operation supplants the hysterorrhaphy entirely. Two of the women I have delivered. The scar showed no tendency to break, and during gestation neither attempted to abort. I have not been able to trace all the cases, and others may have become pregnant.

I have always considered hydrosalpinx and broad-ligament cysts as perfectly innocent affairs. The cul-de-sac method furnishes a safe way of dealing with them without removal.

All infections do not result in pyosalpinx, but often nothing is left but firmly adherent and closed tubes. These women suffer a great deal at times from spasmodic pain. Not the gross lesions as found by examination, but the subjective symptom, pain, brings them to the operating table. Coeliotomy appears too severe an operation for dealing with merely occluded and adherent tubes. The cul-de-sac operation enables the surgeon to sever all adhesions and to open these agglutinated fimbriae.

We are approaching the position in this work which calls for a halt and review of what we have previously done. There can be no question that it is much more satisfactory to the surgeon to make a clean radical operation of every case of pus in the pelvis which he meets. But, viewed from the standpoint of the woman, the sudden artificial menopause is about as distressing as the pus tubes. This is especially true when young women, who have never had children, are spayed. In such cases, then, I believe our surgery must be modified by extraneous circumstances very largely, and if we can afford that measure of relief which will enable these women to be up and about and still menstruate, we have done our full duty to them. Cure them symptomatically and leave them physiological, partially at least!

The cases numbered 13, 14, 15, 16, 19, 20, 22, 23, 24, and 26 were all treated by the conservative vaginal section, no structures being removed. This method must not be confounded with the trocar puncture. I always make a very wide incision in the cul-de-sac, and split open the pus sacs so that they can be packed with gauze.

When nature effects a cure of repeated inflammations, it is by means of a fibrosis of the tissues. We see such tissues in old whores who have had many attacks of gonorrhœa and many applications of curette and caustic. Now, in this cul-de-sac work on pus tubes we attempt to secure an obliteration of the affected tube.

I have designated my gauze packing a pelvic Mikulicz, as the best descriptive term. The gauze is packed tightly into the pelvis, to act not as a drain, but as an occluding dressing.

Eight months after the cul-de-sac operation I did a suprapubic hysterectomy upon Case XXIII. I found both tubes practically masses of fibrous tissue. The right ovary was attached high at the pelvic brim to a diseased appendix vermiformis. It was the abdominal rather than the pelvic lesion which indicated the radical operation.

Pyosalpinx of one side I have treated through the vagina, removing the tube between forceps. I do not like the operation. I had opportunity to see the result of this work also. In Case XXII. I carried my conservatism too far in my attempt to save the left tube. The patient subsequently, months afterward, developed a pyosalpinx on the left side. When the hysterectomy was done, I found the area of first interference per-

fectly smooth and no evidence of recent lymph about the right stump. I do not like to put forceps in among the intestines, even though they be surrounded by gauze. Should they touch the intestines, slough would probably result within a few hours. As for ligatures, we cannot apply these sufficiently close to the cornu to be safely effective.

If we dissect the bladder away from the uterus, we can get at the cornu from in front and tie off a pus tube. But the traumatism here is more severe than with cœliotomy. In the present state of our knowledge, it is wiser to remove single pyosalpinx through the abdomen.

The exploratory cul-de-sac operation adds nothing to the danger of the cœliotomy. It rather lessens it by furnishing a perfect drainage space.

The fact that I have, in five of my cases, been enabled to demonstrate the vermiform appendix through the cul-de-sac indicates a possible way to evacuate appendiceal abscesses in women. These abscesses are so usually associated with pyosalpinx that the surgeon in approaching them by the usual laparotomy incision, does not empty the entire pus formation. He could do this from the cul-de-sac without difficulty.

There have been a number of cases of pus tubes which I have subjected to suprapubic operation, having shown through the cul-de-sac that the lesions were abdominal in their importance because of important intestinal complications.¹

The vaginal hysterectomies were for all the various conditions of pus in the pelvis, except a pus tube opening into the intestine. Since beginning my vaginal work, I have not met with one of these. Sometimes I split the uterus, but more often I leave it entire, so that my intra-uterine traction forceps can hold. I never make the Ségond incision, as I believe it displaces the uterine arteries, as well as the ureters. I make my incision behind the base of the broad ligaments (Fig. 1) and then carry it around the cervix. Having separated the bladder above the level of the ureters, I introduce the index fingers of both hands into the cul-de-sac and the middle fingers between the bladder and uterus, and gradually separate the two hands. In this way, I force the bladder and ureters outward without disturbing the vascular supply of the uterus.

But in diffuse pelvic suppuration, and in certain other cases, the difficulties must be divided by splitting the uterus in two. We can, in this way, deal with each side separately.

My method of dressing these cases is radically different from that employed in France. The French surgeons use two narrow strips of gauze as drains.

When I have completed my operation, I make a careful ocular inspection of the pelvis, the table being in Trendelenburg's position. If there be no bleeding points, I put in one piece of folded gauze between the forceps of each side and the vagina. I then pack in the gauze in squares, one end being up as high as the tips of the forceps, and the other in the vagina. From four to eight of these pieces are necessary to fill the vagina and pelvis. But if vessels are found leaking, small anastomotic branches other than the ovarian and uterine trunks, I put the gauze in as follows:

Having protected the vagina against forceps pressure, as before, I insert one square of gauze alongside one pair of forceps and against the oozing points. I then take the long Péan narrow retractor (it is good for nothing else), and crowd this piece of gauze hard against the forceps and side of the pelvis. Another piece of gauze is put in, the retractor removed and placed over this square of gauze, and it is also crowded hard against the other piece. In this way, alternately inserting the squares of gauze and pressing them

together against the side of the pelvis, when we insert the last piece and remove the retractor for the last time, we have a column of dressing from one set of forceps to the other, which exercises hæmostatic pressure from one lateral pelvic wall to the other. If one likes, he can use enough pressure to control the iliac arteries. The important point is to get the pressure from side to side, rather than between the movable, hollow viscera, bladder, and bowel. The uterine artery could be perfectly controlled in this way.

I remove the forceps in two days. The first dressing comes out under a chloroform narcosis of a few minutes, on the eighth to fourteenth day. Each piece of gauze is put in as a square, is four inches wide and a yard long, so that when the eight pieces are inserted there is an abundance of absorbant dressing to remain over a week. The self-retaining catheter comes out with the forceps, after washing the bladder.

In reviewing this work as a whole, the greatest satisfaction is felt upon contemplating the five cases of puerperal septicæmia and the cases of pus in the pelvis conservatively treated. I am almost inclined to state that a hysterectomy should not be done until this cul-de-sac evacuation of pus and pelvic Mikulicz packing have been tried and failed.

Not a case in this series would have been treated a few years ago in any way other than by cœliotomy. In many parts of Europe and, I regret to say, in certain American cities, very many of those cases would have been subjected to hysterectomy, which I have avoided. The two women who have borne children would have been castrated if cœliotomy had been done. Every one of the adherent retroposition cases presented more or less marked tubal involvement. They have all got their tubes and ovaries, except in Case VII. in which the patient was subjected to a necessary hysterectomy eight months later. But if the reader considers me extreme in my conservatism, I would like to offer him the following proposition: the evacuation of purulent sacs in the pelvis with the use of properly applied dressings, will symptomatically cure eighty per cent. of such cases, and will preserve the menstrual function to them all; the cases not so cured are relieved of acute symptoms, and the radical operation can be done at the elective time.

When I meet with a case of pus in the pelvis, I always think that the man who first saw the patient is to blame. The way to stop operations like hysterectomy for pus is to prevent suppuration. When I have to do a hysterectomy in a pus case, I must admit to a sense of humiliation very often. The sooner we recognize that pelvic inflammation is a surgical disease and should be surgically treated, the better for women. The application here of the great surgical truth, that the way to check infection is by cutting off the original source of infection and draining away its complications, is beautifully illustrated in half my cases.

And, given anything like a decent chance, the wonderful reparative power of the pelvic viscera will bring about a symptomatic cure, at least.

The day is passed when he who gives opium and comforting words for peritonitis can be secure. The responsibility is too great to assume.

Urination after Labor.—1. Urination after labor, in the majority of cases, follows spontaneously. 2. Catheterization is but exceptionally required: if it be necessary, it should be deferred as long as possible. 3. It is only indicated when the bladder assumes abnormal proportions, or if retention occurs. 4. Catheterization is liable to occasion two evils—cystitis, in spite of all precautions, and dependence of the bladder for a time upon the catheter.—N. RECHT, *Rev. Internationale de Bibliog. Méd.*

THE IDEATIVE FACULTIES AND SELF-CONSCIOUSNESS IN THE LOWER ANIMALS.

BY JAMES WEIR, JR., M.D.,

OWENSBORO, KY.

WITHOUT entering into a detailed exegesis of what mind is, it may be safely affirmed that mind, in some form or other, exists not (as is erroneously believed by the masses) in the brain alone, but throughout the entire animal organism. It can be easily demonstrated that muscle, even when separated from the body, has memory and that it retains this function of the mind until morbid, degenerative, lethal, or putrefactive changes set in; likewise, it can be easily shown that throughout the organism there are scattered many brains (ganglia), which, in some of the lowest animals at least, do not differ histologically from those that are recognized as being true brains. Recent microscopic investigations lead me to believe that certain of these ganglia or pseudo-brains are the centres of senses not possessed by man; for instance, the sense of direction (homing instinct) and the sense of mute, though absolutely intelligent, communication. It is not the purpose of this paper, however, to enter at this time into a description of the histological characteristics of these ganglia, nor to detail the experiments made by myself in my endeavors to locate sense centres. I wish rather to call the reader's attention to some original observations in the psychology of the lower animals, by which I propose to demonstrate the fact that animals exceedingly low in the scale of life, as well as animals high in that scale, give unmistakable evidences of ideation, ratiocination, and even of abstract thought. This last quality of the mind, abstract thought, has been heretofore considered distinctly and distinctively a possession of man alone of all created beings; but I hold and think it capable of demonstration that all animals in which are to be found cerebra, cerebella, optic thalami, and corpora striata, and in which the phenomena of dreaming are noticeable, are able to engage in abstract thought to a certain extent. Some of the higher animals are, in my opinion, in a measure self-conscious—the degree of self-consciousness approximating that of an infant of two and one-half or three years. The foregoing propositions will be discussed in their proper turns as they are brought out in the progress of this paper.

Memory of locality, of route, is to be found in many animals of exceedingly low organization. While engaged in watching a water louse, I saw it swim to a hydra, tear off one of its buds, and then swim some distance away to a small bit of mud, behind which it hid until it had devoured its tender morsel. Again it swam back to the hydra, and again plucked from it one of its young; again it swam back to the little mud-heap, behind which it once more ensconced itself until through with its meal. When we remember that this little creature was among entirely new surroundings (for I had dipped it from a pond in a tablespoonful of water which I had poured into a saucer), we will appreciate the fact that the water louse evinced conscious determination and no little memory. It probably discovered the hydra accidentally; it then, as soon as it had secured its prey, swam away, seeking some spot where it could eat its food without molestation. But when it sought the hydra again and then swam back to its sheltering mudheap, it showed that it remembered the route to and from its source of food supply and its temporary hiding-place.

H. J. Carter, F.R.S., says, in his "Annals of Natural History," that he once saw an actinophrys approach a ruptured fungal cell from which starch grains were escaping. It seized one of these starch grains and went to some distance away, where it incepted it. It then returned to the ruptured cell and obtained an-

other starch grain, which it carried off in a like manner. "All this," says he, "was repeated several times, showing that the actinophrys instinctively knew that those were nutritious grains, that they were contained in this cell, and that, although each time after incepting a grain it went away to some distance, *it knew how to find its way back to the cell again which furnished this nutriment.*" I have taken the liberty of italicizing a portion of the above quotation, for it is certainly a most wonderful instance of memory of route in an animal of such minute size and low organization. This entertaining writer and close observer also writes as follows in the above-mentioned book: "On another occasion I saw an actinophrys station itself close to a ripe spore cell of pythium, which was situated upon a filament of *spirogyra crassa*, and as the young ciliated monadic germs issued forth, one after another, from the dehiscent spore cell, the actinophrys remained by it and caught every one of them, even to the last, when it retired to another part of the field, as if instinctively conscious that there was nothing more to be got at the old place."

At the base of the large terminal ganglion in the neuro-cephalic system of the common garden snail, lying immediately below and between its two "horns," will be found, I am satisfied, the centre governing its sense of direction. For, when this portion of this ganglion is destroyed, the snail loses its ability of returning to its home when carried only a short distance away; otherwise, it can find its way back to its domicile when taken what must be to it a very great distance away, indeed. Beneath the stone coping of a brick wall surrounding the front of my lawn, and which, on the side toward my residence, is almost flush with the ground, many garden snails find a cool, moist, and congenial home. Last summer I took six of these snails, and after marking them with a paint of zinc oxide and gum arabic, set them free on the lawn. In time, four of these marked snails returned to their home beneath the stone coping; two of them were probably destroyed by enemies. Again the same number of snails were marked, after the base of the above-mentioned ganglion had been destroyed, and likewise set free. Although they lived and were to be observed now and then on the trees and bushes of the lawn, none of them ever returned to the place from which they were taken beneath the stone coping. I have performed this experiment repeatedly, always with like results.

The ant has the sense of direction in a marked degree, and, although I have not exactly located its centre, am convinced that it is to be found at the base of the cephalic ganglia. It is very interesting to watch a marked ant during her journey back to her nest, after she has been carried away and placed among unfamiliar scenes and surroundings. At first, owing to her fright, she will dash away helter-skelter; but soon recovering, she will head in the direction of home, and moderate her pace until she creeps along at a very cautious and circumspect gait indeed. Every now and then she will climb a tall grass blade or weed and take observations. After a while, she sees certain landmarks, and her speed becomes faster; soon the surrounding country becomes familiar, and she ceases to climb blades of grass, etc.; now she is in the midst of well-known scenes, and at last she fairly races into her nest.

In this instance the ant is led at first by her sense of direction alone; as soon, however, as she comes to country which she has hunted over and with which she is familiar, memory comes into play and the sense of direction ceases to act, or, if it acts at all, it acts unconsciously. Bees, wasps, and some of the beetles, likewise, have the sense of direction highly developed, as do most of the mammalia. The habit that some

animals have of returning to their homes from great distances is well known, and I do not propose, therefore, to enter into details concerning it; yet the following instance is so unique that I cannot refrain from mentioning it. In the fall of 1861, if I remember the year correctly, a gentleman living in Vincennes, Ind., went to visit his father at Lebanon, Ky. When he started back home his father gave him a yoke of steers, which he drove to Vincennes *via* Louisville, Ky. Shortly after his arrival home the steers escaped from the field in which they were confined, made their way to the Ohio River, which they swam at Owensboro, Ky., one hundred and sixty miles below Louisville, and in a week or so were discovered one morning at the gate of their old home at Lebanon. Led by their sense of direction alone, for they were young and had never been off the farm at Lebanon until their owner gave them to his son, they made their way home, several hundreds of miles, over a route utterly unknown to them.

It is a well-known fact that many of the higher animals remember individuals for long periods of time, when they are separated from such individuals for such periods of time and are then again brought in contact with them. It is not generally known, however, that some of the lower animals likewise possess this psychological trait, and yet they do.

For several months a large black hunting-spider lived beneath a table in my room, and it was my custom to give her, daily, crippled flies and other insects. She soon became very tame, would come out on the table as soon as I entered the room, and would even take food from my fingers. She would come out, also, when other persons entered the room, but would dart beneath the table as soon as she discovered that it was not I, thus showing that she recognized me as an individual. I was absent from home for a week, but this spider recognized me as soon as I came into the room on my return, clearly indicating that she had remembered my individuality for a week at least.

Again, a friend sent me two Floridian chameleons, which dwelt in my desk and which in course of time became very tame. My desk is a combination book-case and writing-table, and these creatures passed most of their time among the books, changing color so perfectly, especially when alarmed, that it took a very sharp eye indeed to descry them when they were quiescent. When I sat at my desk writing they would jump down on my head or shoulders and explore my entire body, running here and there and everywhere about me, sometimes tickling me with their sharp little claws until I, too, was forced into making a voyage of discovery, in order to bring them once more to the light. But let a stranger enter the room, and, presto! they were gone in the twinkling of an eye. I left home on one occasion and was gone for two months. When I came into my room and sat down at my desk, I looked about for my little pets, but could not see them. I had come to the conclusion that they had either died or escaped from the room, when suddenly I saw a tiny little head peep out from between two books and as suddenly disappear. I pulled out a writing-pad and went to work, keeping a watch, however, for my shy little friends. They gradually became bolder and bolder, until all at once they seemed to recognize me, first one and then the other leaping to my shoulders. In a few moments they were making their usual voyage over my person. In this instance these lizards remembered me after an absence of at least two months; it took them about two hours to fully recall my personality, yet they did it in the end. Some insects have such good memories and are so amenable to instruction that they can be taught to perform little evolutions, draw miniature vehicles, feign death, etc., at the command or signal of their trainer. There are

many people alive to-day who witnessed the performances of a troupe of trained fleas, which was on exhibition in the larger cities of the United States some thirty or forty years ago. Great must be the intelligence of a creature so minute to learn to do things so utterly foreign to its nature, and greater still must be the memory which could retain and remember such instruction for days, weeks, and months!

Instinct is, in a certain sense, a process of ratiocination, though its immediate operations may not be due to reason. Instinct involves mental operations; if it did not it would be simply reflex action. It is heredity under a special name; the father transmits his mental peculiarities as well as his corporeal individualities to his offspring. The experiences of thousands of years leave their imprint on the succeeding generations, until deductions and conclusions drawn from these experiences no longer require any special act of reason in order to bring about certain results. These results, which were at first the outcome of special acts of ratiocination, or accidental happenings leading to the good of the creature or creatures in which they occurred, finally become habitual or instinctive.

These special acts of ratiocination are of daily, of hourly occurrence in the lives of countless myriads of the lower animals, and which escape our observation because of the obtuseness of our senses. Every now and then, however, the observer is able to chronicle such an act of reason, and thus adduce the proposition that if the creature or creatures were continually placed in surroundings requiring a like act of reason, that act would eventually become habitual and instinctive on the part of that creature or those creatures. I have witnessed hundreds of acts of intelligent ratiocination in the lower animals that were not called forth by experience and which had not a single factor of heredity. For instance, several years ago I noticed that one of the combs in a beehive, owing to the extreme heat, had become melted at the top and was in great danger of falling to the floor. The bees had noticed this impending calamity long before I had, and had already set about averting it. They rapidly threw out a buttress or supporting pillar from the comb next to the one in danger, and joined it firmly to it, thus shoring it up and preventing its fall in a most effectual manner. When they had made everything strong and secure, they went to the top of the comb and re-attached it to the ceiling of the hive. After this had been done to their satisfaction, they removed the shoring pillar and used the wax elsewhere. In this instance, there was an immediate adaptation of themselves to surrounding circumstances, in which they averted and prevented an utterly unforeseen and unheard-of catastrophe by means as effectual as they were intelligent. Could man do more or reason better? Here was an experience which had not happened to them in hundreds and hundreds of generations perhaps; which perhaps had never happened to them before, and yet when it did happen their quick intelligence readily grasped the situation and they at once set about remedying the evil.

The higher animals, such as the dog, the cat, the horse, the monkey, etc., are continually giving evidences of acts of special ratiocination, in which instinct plays no part. They are of such common occurrence that "he who runs may read;" therefore, I will here give only one, an instance of intelligent ratiocination in a dog, whereby the animal saved its life. The following is from a letter that I received from a friend: "The dog, a water spaniel, had gone after a stick flung upon the ice of a pond about twenty feet distant from shore. The water was about five feet deep. The ice gave way. The dog went under the water several times in swimming about the enlarged space made by attempting to regain the surface

of the ice, which gave way under his weight. He became thoroughly chilled by much confused swimming about in a circle, seeking some point at which the ice would bear his weight. I reached a limb to him, and calling him by name shortly got his attention. He placed his paws upon the ice and seemed to listen intently as I extended the limb toward him, the ice, meanwhile, sinking under his weight as he looked at me. He caught the limb between his teeth and I assisted him by pulling him toward me upon the thicker ice inshore. Finally, the ice became strong enough about fifteen feet from shore to sustain his weight. So, still with his teeth locked on the stick, I pulled him on the thicker ice and across the surface to the shore." I learned from my friend that the dog was completely exhausted when he reached shore and remained prone upon the ground for quite a while. He would have been drowned unquestionably had he not recognized and seized the only available means for saving his life.

It will be exceedingly difficult, if not altogether impossible, to demonstrate positively and absolutely that animals lower than man possess the faculty of abstract thought, yet analogically and inferentially the proposition is of easy demonstration. Man possesses two kinds of consciousness—an active, vigilant, co-ordinating consciousness, the seat of which is in the cortical portion of the brain; and a passive, pseudo-dormant, and, to a certain extent, incoherent and non-co-ordinating consciousness, whose seat is in the great ganglia at the base of the brain, viz., the optic thalami and corpora striata, and in other ganglia situated in the spinal cord and elsewhere in the body. We can readily prove the truth of this by observing certain phenomena which are to be noticed daily among ourselves. A man falls into a "brown study," loses himself in abstract thought, and if gently approached without being startled he may be asked questions which he will answer intelligently without any conscious act on his part. His ganglionic consciousness for the time being holds him beneath its sway, yet his active consciousness is not so much obtunded but that he can answer questions intelligently. My fox terrier has a brain which in all essential particulars does not differ from that of man; my observation teaches me that his mind, so far as memory and the emotions are concerned, is the same in kind though not in degree as that of man. I am also convinced by actual experimentation that he falls into "brown studies" just as man does; therefore, why deny him the possession in some degree of the faculty of abstract thought? I do not mean to say that my dog can commune with himself in regard to ethics and aesthetics; his power of abstract thought is in its embryonic state, for I am more than convinced that it has passed through its germ state.

Again, when active consciousness is stilled in slumber, subconsciousness or ganglionic consciousness sometimes remains awake and makes itself evident in dreams. The lack of rational thought co-ordination in subconsciousness is shown by the more or less extravagance and incoherence of dreams. Everything, no matter how unnatural and extravagant, occurring to the dreamer is accepted by him as being natural and consistent; when, however, his active consciousness is aroused, he at once recognizes the incoherence of his dreams. I hold emphatically that all dreams, when closely studied, will show extravagance and incoherence; a dream may seem at first glance to be entirely coherent, but if the remembrance of the dream be perfect and it be closely studied, numerous incoherences will always be discovered.

Many of the higher animals dream, notably the monkey, the cat, and the dog. I have repeatedly observed my dog while he was under dream influence, and have

even been able to predicate the substance of his dream from his actions. Like man, the dog is unable sometimes to differentiate between his waking and dreaming thoughts; he confounds the one with the other, and follows out in his waking state the ideas suggested by his dreams. This with man is always a momentary delusion; with the dog, however, it may last for a minute or two. Thus, I have seen my dog chase imaginary rats around my room after being aroused while in the midst of a dream. His chagrin when he "came to himself" and saw me laughing at him was always strikingly apparent. Finally, I have seen my dog, seemingly after giving the subject some thought, jump up and rush out to the stables and engage in a hunt after rats. The quality of abstraction in such ideation is not very high, it is true; nevertheless, it is present to a certain extent.

To prove that self-consciousness is present in some of the higher animals is even more difficult than is the demonstrating of abstract thought in such animals; yet, inferentially and analogically, it can be done. Inference and analogy are powerful and legitimate *instrumenta logicorum*, and should, therefore, carry with them great weight.

Many of the higher animals recognize to a certain extent the rights of property. For instance, in 1879, two very intelligent chimpanzees were on exhibition at Central Park. One of these animals claimed as her property a particular blanket, and, notwithstanding the fact that there were other blankets in the cage in which they were confined, always covered herself with this blanket. She would take it away from her companion whenever she wished to use it. Again, two turkeys on my place deposited their eggs in the same nest. The hen which first built and used the nest regarded the spot as her individual home; therefore, whenever she found the other hen's egg in the nest, she would break it with her beak and then carry it some distance away. This I have seen her do repeatedly. Many dogs and cats regard certain rugs, cushions, etc., as their own property, and resent any interference with them. It seems to me, that in all such instances these animals regard themselves as individuals; that they recognize the psychical as well as physical difference between the *ego* and the *tu* part as soon as they begin to regard things as property. I do not mean to say that their self-consciousness reaches the exalted state as that which is to be found in mature man. I do mean to say, however, that it approximates that of infants of two and one-half and three years. Anthropologists hold that as soon as man began to recognize property rights he took a gigantic mental stride, and in proof of this proposition they cite the mental degradation of those races which have not arrived at such knowledge. From this analysis of mind as it is to be observed in the lower animals, I deduce the conclusion that it is the same in kind as that of man, though differing in degree.

Salaries of Medical Teachers in Vienna.—The Vienna correspondent of *The Lancet* says that a bill has been submitted to the Austrian legislature the object of which is to increase the salaries of the professors in the universities of the empire. Hitherto there have been three scales—namely, \$900 a year for the professors in Vienna, \$830 for those in Prague, and \$775 for those in other towns, the professor also receiving fees for his lectures. In Austria lectures are delivered five times a week, and the fees are fixed at \$2.50 a half-year. Teachers have now the choice between the above salaries with the fees for lectures and the augmented salary with gratuitous lectures, which has been fixed at \$1,330, \$1,500 and \$1,685. "Extraordinary" teachers will be paid \$665 and the priv-docents will be unpaid, as hitherto.

CEDEMA IN GRAVES' DISEASE—REPORT OF A CASE OF CEDEMA OF THE EYELIDS—THYROIDECTOMY.¹

By J. ARTHUR BOOTH, M.D.,

NEW YORK.

BESIDES the three diagnostic symptoms usually found in Graves' disease, there are a number of others which, added to this well-known triad, finally present a symptomatology at once unique, mysterious, and of extreme interest. Although these other seemingly unimportant symptoms have attracted less attention than those by which the disease is sometimes designated—namely, exophthalmic goitre—one of them, œdema, is perhaps worthy of further consideration.

These various forms of swelling may be described as consisting of three varieties: (1) Œdema of cardiac origin. It may be due to mitral disease coexisting with Graves'. (2) Œdema of nervous origin, as is seen in slight swelling of the insteps and lower legs, which does not tend to increase. Valvular lesions of the heart are absent. (3) Transitory œdema. This is the rarest class, the œdema here being limited to various parts of the face, neck, arms, and hands. The cheeks and eyelids are favorite positions, and sometimes both limbs of one side of the body may be affected. In discussing this symptom it will be convenient to consider it (1) as commonly met with, and (2) its occurrence in what I deem a rare locality, the eyelids.

(1) It consists in a circumscribed swelling or puffiness, not pitting on pressure, not stationary, and in most cases confined to the ankle, upper part of the foot, or lower part of the thigh. Sometimes the œdema may be general over the whole body, but generally it is circumscribed. Rendu saw it in the supraclavicular and Germain Sée in the infraclavicular hollows; Burton, Baumler, and O'Neil in the ankles; Millard and Benedikt upon the hands; Osler and Reinhold on the face, neck, and hands. Slight swelling of the ankles and feet has been observed in one-third of the cases by Arthur Maude. Millard collected ten cases. In one of these, a very severe form of œdema of the lower part of the body suddenly appeared, and after three weeks' duration passed away simultaneously with the onset of an acute attack of diarrhœa. Marie noted its presence in the legs in two cases, and in one the swelling reached to the umbilicus. Möbins calls attention to its occurrence in the lower extremities. Besides those cited by the above authorities, cases are reported by West, Stierlin, O'Neil, Goix, and Buschan. In none of the cases did examination show any evidences of varicose veins or kidney disease.

Judging from the above data, it appears evident that œdema is frequently present in Graves' disease, although from a perusal of our own literature on this subject one would be justified in forming an opposite opinion. In twenty-seven cases seen by the writer, this symptom was noted in only one, and in this patient the swelling consisted of a slight but distinct puffiness of the dorsum of the hands.

Various reasons have been given and theories formulated in explanation of these dropsies. According to Marie, it is not to be explained by the existence of a cardiac lesion; it being sufficient to have *une fatigue du cœur*, or a tendency to dilatation, which is common in Graves' disease. Bienfait and Debove ascribe this symptom to asystole; Germain Sée and Möbins to peripheral vasomotor disturbance. Maude states that these forms of localized œdema are evidently of neuropathic origin, and are, in fact, manifestations of

peripheral neuritis; also to be compared to the conditions described as hysterical neuritis. The comparison is also striking between these localized cedemas and those seen in beri-beri, which is clearly a peripheral neuritis.

(2) I wish now to speak of the presence of this symptom in the eyelids. Its occurrence in this locality is rarely seen, and attention has been called to it by only a few authorities. R. Vigouroux¹ says that false œdema of the eyelids is a frequent symptom, and ascribes the swelling to a paresis of the orbicularis; stating that when contraction of that muscle is affected by an electric current the swelling disappears, driven back by the pressure of the subcutaneous fascia. In contradiction to this statement, I may add that in the patient I am about to present repeated trials by electricity brought about no such result. Hector Mackenzie² found the eyelids œdematous in five cases, all of old standing. Gowers³ mentions the occurrence of swelling of the eyelids in a patient after apparent recovery from other symptoms.

With this brief reference to the bibliography of the subject, I take pleasure in presenting a patient in whom this œdema of the eyelids is present to a marked degree, although the exophthalmos is hardly noticeable. The history is as follows:

Nellie C—, aged seventeen; single; seen November 5, 1895. When six years old a sister, taking her in her arms, made a pretence of throwing her out of the window. She was very much frightened, and an attack of what was called brain fever followed. She was confined to the bed for several months, and during this time had a number of convulsions, but finally made a good recovery. She remained well until the appearance of menstruation six years later; about this time, when thirteen years old, a swelling of the upper lids of both eyes was noticed, which has gradually increased and now has become so noticeable as to attract attention. This symptom is more marked in winter than summer.

She now complains of frequent attacks of palpitation of the heart, accompanied by throbbing in the neck and profuse perspiration; also of general nervousness and occasional headache. She has neves

¹ Read before the American Neurological Association, June 5, 1896.

² Progrès Médical, 1887.

³ Lancet, 1890.

⁴ "Diseases of the Nervous System," vol. ii.

noticed any prominence of eyes, enlargement of the neck, or swelling of the hands or feet. On examination the patient presents the appearance of a case of Graves' disease. When we examine the eyes, however, no exophthalmos is discovered, but, instead, a very marked and peculiar œdema of both upper lids, as is shown in the accompanying photograph. It is not a true œdema; no pitting follows pressure and it does not cause the closure of the lids, such as is produced by ordinary œdema. Movements of the eyes and lids are harmonious. On inspection there is no decided prominence of the thyroid gland, but on palpation swelling and a diffused hardness of both lobes is made out. The heart action is agitated and pulse rate rapid, averaging 120 beats to the minute. With the exception of loud hæmic murmurs at the base, the heart is normal. Face, neck, and both hands are covered with beads of perspiration. There is a slight tremor of the fingers.

(One month later (December 5th) prominence of the left eye appeared. Having been unable to do any work for some time, even to the attending of minor household duties, the patient willingly consented to operative interference, and on December 15th she was admitted to St. Luke's Hospital, where a few days later the right lobe of the thyroid was removed by Dr. B. F. Curtis. Her recovery from the effects of the operation was rapid and the progress of the case up to the present time has been entirely satisfactory. It is now six months since the operation, and during this time there has been a complete disappearance of all nervousness; the throbbing and palpitation have ceased, and with two exceptions the pulse has not been above 90, most of the time varying between 80 and 86. Although the improvement in the symptoms just mentioned has been marked, the peculiar œdematous swelling of the eyelids still persists, that of the left being greater than before the operation.

Conclusions.—The following conclusions may be legitimately drawn from this brief contribution: (1) Slight degrees of œdema, situated in the extremities, are of common occurrence in Graves' disease, but this symptom limited to the eyelids is very seldom seen. (2) In distinguishing these various forms of swelling, it is necessary to be guided by the position and degree. If situated only on the face and upper limbs, or if unsymmetrical, it is entirely of nervous origin, and it may be so if it affects the feet, but it is only slight and temporary. (3) These dropsies are evidently of vasomotor origin and are probably due to a paralysis of the vasoconstrictor nerves, manifestations of peripheral neuritis. (4) Limited to the eyelids, it may be due to a paresis of the orbicularis. If this be true, however, it is strange we do not meet with it in other palsies of this muscle. (5) Thyroidectomy, carefully performed and by one cognizant of the occasional complications, is not such a dangerous operation as is generally believed. (6) From operative interference in Graves' disease we may expect an improvement in the rapidity of the pulse, cessation of the disturbing attacks of palpitation, and a cure of many of the subjective phenomena.

Gold Combinations.—1. The chloride of gold and sodium of commerce, so called, is not such in fact, but merely chloride of gold mixed with chloride of sodium; therefore for any chemical purpose chloride of gold only need be considered. 2. Chloride of gold is an extremely unstable compound, its identity being readily destroyed by light or air, while the addition of the least amount of organic matter will almost instantly convert it into albuminate, which upon contact with the mucous membrane or skin surface (albumin being thus formed) is extremely difficult of solution—T. H. STUCKY.

ELIMINATION, ANTISEPSIS, AND STARVATION IN THE TREATMENT OF TYPHOID FEVER.¹

By H. S. McCONNEL, M.D.,
NEW BRIGHTON, PA.

THAT typhoid fever is a self-limited disease, that the system having absorbed the poison the disease must run its course through the different stages, I do not believe, and the physician who now treats this disease on the so-called rational or let-alone plan, is as criminally negligent as the surgeon who to-day in treating wounds ignores asepsis. This may seem a bold and unwarranted statement, yet if it is not true, all the time, labor, and money spent in the bacteriological study of typhoid fever have been in vain, our conclusions erroneous, and the bacillus typhosus is a myth. Accepting the micro-organism theory, believing that the point of attack is in the alimentary canal, that the characteristic symptoms are due to the absorption of the toxin, and are the result of the local activity of the specific bacilli, and that a case is grave or mild dependent upon the quantity of said toxin in the blood, are we not compelled to grant the truth of the above?

If Eberth's bacillus is the cause—the corroboration of Elsner's observations seems to place this beyond doubt—and it is ably assisted by the bacillus coli communis, a treatment based upon this pathology and directed to the exclusion and annihilation of these bacilli is certainly a rational one, and when pathology and treatment go hand in hand with a diminished death rate, and at the same time the patients are more comfortable than by any former methods, we are certainly justified in the above statement.

To fulfil all the indications there are three essential features that we must bear in mind.

First, the prevention of the introduction into the digestive tract of any specific bacilli.

Second, expulsion and destruction of all bacilli in the alimentary canal, and the elimination of the products of their labor.

Third, rendering the canal thoroughly aseptic, making it sweet and clean, and keeping it, as nearly as possible, in this condition.

The first is best accomplished by permitting nothing but boiled water and the remedies to enter the stomach, and by keeping the mouth, teeth, nostrils, hands, finger nails, whiskers, and the excretory outlets aseptic. The latter precaution is very important, and these parts should be thoroughly washed after each evacuation. The room must be cleared of all unnecessary articles of furniture and clothing, and all vessels must be kept surgically clean. Milk or any kind of food should remain in the room no longer than is required. The apartment should be well lighted and the temperature not above 65°.

The second object can be accomplished by giving three five-grain powders of calomel at hourly intervals, followed with Rochelle salts until there is free catharsis. The patient must have no less than two free passages every twenty-four hours during the fever. If the salts and an occasional dose of calomel will not do this, we must resort to some more active cathartic. Though contrary to what we were all taught, and what is still being taught, purgatives reduce to a minimum the liability to hemorrhage or perforation. The ulceration of Peyer's patches is not typhoid fever. It is caused by the direct irritation of the bacterial poison, and, as Professor Thistle has so ably demonstrated, the extent of the ulceration is in proportion to the degree of concentration and duration of contact. By purgatives we increase the quantity of the intestinal fluids,

¹ Read before the meeting of the Society of the State of Pennsylvania, at Harrisburg, May 19, 1896.

dilute the toxin and expel it, and thereby decrease the danger from its local action upon the glands; we restrict blood contamination, reduce the number and activity of the bacilli, and permit the restoration of the disabled tissue.

The third indication is met by guaiacol, salol, or any of the other intestinal antiseptics. For the first few days I prefer salol, after that guaiacol. An enema morning and evening, of a large quantity of salt and cold water, must be given regardless of the condition of the bowels. All food, and this includes milk, must be prohibited for three days. Recent investigations prove that in typhoid fever very little, if any, hydrochloric acid or pepsin is secreted, and Professor Thompson says the stomach is similar to that of a new born babe's. Yet in the discussion of typhoid fever a few weeks since before the Cleveland Medical Society, one of its members said he endeavored to have all his typhoid patients take nine pints of milk in twenty-four hours, and in a large number of cases the daily average was over eight pints. Jenner says that a pint of milk is equal to a full-sized mutton chop. Think of it! nine mutton chops to a fever patient in one day. Is this not absurd? Is it not injurious? Is it not malpractice? And, to make it worse, this is forced upon a patient who, except in rare instances, has no appetite, who even loathes the sight or taste of food. If a strong, active, and healthy laborer was to consult you about some uncomfortable feeling in his stomach, and told you he ate nine mutton chops per day, if you did not tell him he was a swine you would think so. Recalling the fact that hydrochloric acid is nature's preventive of putrefactive changes, and the formation of dangerous ptomaines in the digestive tract, we see that a fever patient stuffed in this manner is surrounded with perils so great that the danger from the bacillus typhosus sinks into utter insignificance. The patient is weak from fever and toxæmia, not from want of food. Increased feeding does not imply increased nourishment, but oftener diminishes it from overworking the already enfeebled stomach.

Jenner years ago called attention to the injury from overfeeding, and said he had often seen delirium, fever, and restlessness subside after the expulsion of large curds of undigested milk. It will be said this is retrogression. The starvation plan was active a century hence. Well and good. If you will exclude bleeding, tartar emetic, and salivation, the treatment then was excellent. Over sixty years ago Eberle's treatment was as follows: Plenty of bland drinks, no food, and purgatives; the latter were given to free the intestinal tract of all irritating and poisonous substances, and he preferred the neutral salts as a purgative. That was good treatment then for typhoid fever, and it is one of the elements of the best treatment to-day.

Page upon page has been written upon the injurious effects of the coal-tar antipyretics, and very few upon excessive feeding, yet the danger of the former is small compared with the latter. It is this almost universal habit of overfeeding, cramming the patient with large quantities of concentrated nourishment, that makes antipyretic measures so frequently necessary.

In the MEDICAL RECORD of June 14, 1893, I called the attention of the profession to the beneficial effects in infantile intestinal diseases of withholding all food for twenty-four hours or more, and the giving of hot water ad libitum. The rapid improvement under this method in most cases, the great comfort afforded the little patients, induced me to try it in typhoid fever, and I can assure you that I have no cause to regret it.

Lutton, of Rheims, in 1880, extolled the withholding of food and giving large quantities of water; he would give no nourishment until the beginning of the

third week. He claimed that this prevented the increase of typhoid germs. As I said above, all food must be positively prohibited for three days. After this it may be allowed when the patient is unmistakably hungry. About the fourth day the patient may interpret an empty feeling for hunger, but this is no indication for food. I had one patient seventeen days without food; temperature first week 104° F. in the morning and 105° F. in the evening. This patient had organic heart disease, required no alcoholic stimulants, and made a good convalescence. Another was for fifteen days without food, and thirty-two went from seven to twelve days. They can have all the water they desire, but it must be sterilized, and preferably hot. It should be administered in definite quantities and at regular intervals. The large quantity of water attenuates the poison and assists the purgatives.

Having stated the indications, I shall tell how I meet them. After free catharsis I order twelve powders each consisting of phenacetin and salol, five grains each, and calomel, one-eighth grain, and give one powder every three hours. I do not administer the phenacetin as an antipyretic, but experience has taught me that no drug will relieve the headache and muscular pains so promptly as this. I now give guaiacol in from five to eight drops every three hours, and continue it for some time after convalescence. I order half a teacupful of hot water every hour, and to impress the importance of this I place a tablet of bromide of potash in a tumbler of water and order a spoonful of this to be given in the hot water every hour. When the temperature is under 102° F. I have the body sponged off with cold water every two or three hours. When the temperature is above 102° F. I apply guaiacol to the right iliac region, from five to thirty drops every three hours. It is applied in the manner directed by my friend, Dr. H. G. McCormack, of Williamsport, Pa. In only one case did this fail me, and this one was a case of relapse. While I could not reduce the temperature below 105° F. for over twenty-four hours, no one can tell how high it would have gone had this not been used. Upon speaking to Dr. McCormack of this he argued that it had not been properly applied. Here he is in error, for the same very competent trained nurse had controlled the temperature with this remedy throughout the primary attack, and at the time above mentioned was applying as before and afterward with good results. We applied it hourly for a while and thirty drops each time. It could not have been due to the impurity of the drug, for we used the original package from a thoroughly reliable manufacturer.

When heart sounds are weak I give strychnine nitrate, and in one case I gave one-sixtieth of a grain every hour for six days. After this I gave it every two hours, alternating with whiskey. In two cases with diarrhoea I did not try to stop it. The greatest trouble I have is in keeping the bowels sufficiently open. When the appetite returns any time after the third day I give milk, two tablespoonfuls of milk in two tablespoonfuls of water every three hours; then gradually I allow fruit juice, mashed potatoes, soft-boiled eggs. If for any reason the diluted milk is distasteful I give malted milk. I never order beef tea or any of the so-called extracts, as I believe them harmful in this disease.

In a series of thirty-four cases treated as above I have had one death. This was of a lady of seventy years, who, one very cold day jumped out of bed and sat upon the floor. Lobar pneumonia developed next day and she died on the fifth day. One patient had two relapses, three had each a relapse, and one had a hemorrhage. The average duration of the disease was 18.3 days. This treatment faithfully carried out will materially shorten the duration of the

disease, will give the patient the greatest comfort possible, he will have no tympanites, the tongue will be moist, and there will be very little restlessness or delirium. When convalescence is established he will have a stomach that, from its long rest, will be capable of easily and thoroughly digesting food.

I have avoided saying anything about the Brandt method for two reasons. First, I have had no practical experience with it; second, it is impractical in a country practice. I have faith in it, and believe all that its friends claim for it.

I desire to acknowledge my indebtedness to Prof. W. B. Thistle, of Toronto, who has so earnestly and ably advocated the eliminative method; also to Dr. C. E. Page, of Boston, who gave me the courage of my convictions in withholding food and using hot water systematically; and to Dr. McCormack, who has taught us all how and when to use this valuable drug, guaiacol.

SARCOMA OF THE ANTERIOR MEDIAS- TINUM, WITH REPORT OF A CASE PRE- SENTING A RARE COMPLICATION.¹

By JOSEPH B. POTSDAMER, A.M., M.D.,

PHILADELPHIA.

THE rarity of this affection, the difficulty of arriving at a diagnosis, and the unusual symptom met with in the case I recently had under treatment, are the reasons for introducing this subject for discussion this evening.

The total number of cases of mediastinal sarcomas on record is one hundred and seven, of which forty occurred in the anterior mediastinum, ten in the posterior, one in the anterior and middle, three in the anterior and posterior, eight in the entire, three in the middle, and one in the whole thorax. The reports of the other cases were not complete enough for classification.

Hare, in his study of mediastinal tumors, reveals the fact that out of ninety-eight cases, thirty-one were primary, five secondary; the others were not stated. From the metastatic nature of sarcoma, one would be led to believe that it would be found as a secondary growth in this region, but all observers report to the contrary. In the cases in which other parts of the body were involved, the mediastinum escaped.

Sex is a predisposing cause, three males being attacked to one female. Age has some influence, the largest number of males falling victims between the ages of thirty and thirty-five, females between thirty-five and forty.

Sarcoma is the most frequent form of malignant disease found in this region. Pepper and Stengel, in an elaborate paper on mediastinal tumors, published in the Transactions of the Association of American Physicians, vol. x., demonstrate that cases of cancer predominated prior to the time of accurate histological study; but since then sarcomas are far more numerous. The same authorities assert that it is not always possible to distinctly differentiate between lymphadenomatous and sarcomatous growths.

The metastasis of sarcoma is through the blood-vessels, excepting the small-round-celled variety, which may spread through the lymphatics, this being the usual channel of lymphadenomas.

The lympho-sarcomas are found most frequently; next the round-celled sarcoma; and, lastly, the spindle-celled.

A sarcomatous growth may find its origin in any of the following tissues, named in the order of frequency: thymus gland, pericardium, periosteum of the

sternum, mediastinal connective tissue, and thyroid body. Virchow has pointed out that a sarcoma with a regular outline grows from the thymus gland.

The symptoms of a case of this kind may be negative for a long time. The patient may never present the appearance of a cachexia.

Dyspnoea may be constant, intermittent, or absent. If the tumor is in the posterior mediastinum it is the former; if in the anterior chamber it is apt to be absent, or, if present, to be intermittent, changing with the position of the patient. Pressure symptoms, such as palpitation, faintness, or irregular action of the heart, are never as marked as in cases of aneurism, and are frequently absent. The symptoms are dependent on the seat and size of the growth, and may develop as the case progresses.

Cough is an early symptom in tumors of the posterior mediastinum, but may be absent if the growth is in the anterior. It is usually dry and ineffectual. Occasionally there is a frothy expectoration tinged with blood. Should there be any expectoration it should be subjected to microscopic examination, with a view of establishing the diagnosis. Free hamoptysis may occur. Pain is not frequently met with, as the tumor rarely causes erosion of the sternum and it moulds itself to the other organs, thus avoiding pressure. Fever is never present, unless there is an inflammatory complication of the lungs or pleura. Dysphagia is not to be considered in tumors of the anterior mediastinum.

Physical signs may be negative. The veins of the face and neck may appear turgid, but then the growth will be found of considerable size. The contour of the chest may be altered, one side being larger than the other. The sternum may be prominent. Transmitted aortic pulsation is rarely noticeable.

Percussion is of assistance only in growths of considerable size; otherwise it is impossible to distinguish cardiac and sternal dulness from that of a growth. On auscultation we are apt to find the heart sounds muffled and distant.

The duration of the disease depends upon the symptoms. Death may occur as early as the second month. As long as the local symptoms are in abeyance, the patient may live a long time.

L. A. N—, aged forty-three, married, Bohemian, height, five feet nine inches; weight, two hundred and ten pounds; father of five children, consulted me for the first time on June 14, 1895. I have been his family physician for five years, during which time he never was sick. During the past year I noticed that he experienced difficulty in breathing on slight exertion, but he attributed it to his obesity. He was of regular habits and was a moderate beer drinker. Five months prior to the beginning of this illness, Dr. George Roessler examined him for life insurance. The doctor informed me that the urine was normal but of low specific gravity, and that the heart sounds were slightly muffled, as if the organ was fatty. Otherwise he found the applicant normal.

On my first visit I elicited the following history: Both parents living, old and in perfect health; brothers and sisters all living and well. Patient's last illness began on June 5, 1895. He had pain in the left chest and hypochondriac region and shortness of breath, for which symptoms he consulted a doctor who happened to be in his store. The physician diagnosed pleurisy, and assured the patient that he would be well in a few days, as he was free from fever. The doctor saw Mr. N— every other day, and finding the temperature normal made light of the case. During this time the dyspnoea was increasing and I was called in. On examination I found the patient sitting on the edge of the bed, gasping for breath. Face flushed, expression anxious. Pulse, 100; temperature, 98.6°

¹ Read before the James Aitken Meigs Medical Association, November 21, 1895.

F.; respiration, 44. No œdema in any part of the body. Heart sounds normal, but muffled and distant. No apparent increase in cardiac dulness. Marked dullness on percussion over the left side of the chest as high as the fourth rib. No respiratory murmurs or râles below this line. No râles or friction sounds in any part of the chest. Left lung showed signs of compression. Occasional dry cough. Radial pulses equal.

Diagnosis: Mediastinal tumor of unknown origin with pleural effusion.

Treatment: Liquor ammonii acetatis, two drachms, every hour until copious perspiration set in; then every two hours.

June 15th, A.M.—Patient perspired freely during the night, and decided improvement in breathing followed. Temperature, normal; pulse, 100; respiration, 32. I ordered large doses of acetate of potassium and infusion of digitalis and a saline purge. That evening condition unchanged.

June 16th.—Temperature, normal; pulse, 104; respiration, 40. Patient passed large quantities of urine and bowels moved freely. Breathing very much embarrassed. No change at the evening visit. Dr. Dercum met me in consultation, and on aspiration we drew off one hundred ounces of bloody serum, which was followed by immediate relief. The doctor agreed to the diagnosis.

June 17th.—Temperature, 98.6° F.; pulse, 100; respiration, 20. Patient passed the first good night since he was taken sick. Breathing not at all embarrassed. Careful examination of the chest did not reveal any friction or other abnormal sound. The patient continued to improve until June 25th, when he appeared well but weak. During this time the breathing was normal.

June 22d.—Dr. Dercum re-examined the patient and agreed to the absence of any visible cause for the effusion.

June 25th, A.M.—Examination of the patient's chest showed left lung in normal position and no effusion. About 5 P.M. Mr. N— arose to allow his bed to be arranged, when suddenly he had a return of the dyspnoea. I saw him one hour later. Pulse, 104; temperature, 100.4° F.; respiration, 40. Dyspnoea very bad. Percussion and auscultation revealed the left pleural cavity full of fluid. At 10 P.M., with the assistance of Dr. Strittmatter, one hundred ounces of fluid were withdrawn from the cavity.

June 26th, A.M.—Patient felt well but weak. Pulse, 100; temperature, 100.4° F.; respiration, 24. Dyspnoea returned about 1 P.M., and by 5 P.M. was as bad as ever. On aspiration I withdrew seventy ounces.

From this time until his admission to the Jewish Hospital on June 30th, the dyspnoea gradually increased. Theappings were made between the seventh and eighth ribs, to the left of a line midway between the axillary and nipple lines. Repeated examinations of the urine were made, and it was always found normal, even to the specific gravity.

Dr. Knipe, chief resident physician of the hospital, has kindly furnished me with the history of the case until the time of the patient's death. I will only quote the following interesting facts:

July 3d.—Aspirated and withdrew one hundred and twelve ounces.

July 4th.—Breathing labored. Inserted drainage tube.

July 6th.—Two convulsions. In the afternoon re-inserted a drainage-tube and withdrew forty-eight ounces of fluid.

July 8th.—Patient died.

A study of the temperature chart shows that the morning temperature was normal except on four occasions, it twice being 100.4° F., once 97° F., and once

97.6° F. The evening temperature was above 100° F. on eight different occasions.

Especial attention must be called to the fact of the long interval that elapsed between the first aspiration and the refilling of the cavity, a period of nine days, during which time the patient never suffered from even a slight attack of dyspnoea. Again, we must note the sudden and overwhelming effusion.

A post-mortem examination was made twenty-four hours after death. All the organs were normal in appearance and size. The pleura was healthy and did not exhibit any evidence of a pleurisy or a deposit of sarcomatous tissue. On turning back the sternum a large mass was seen overlying the heart, which appeared as a mass of fat. Careful enucleation of it revealed a tumor of regular outlines, apparently not attached to any of the surrounding tissues. Microscopical examination showed it to be a round-celled sarcoma. From these facts we concluded that it had its origin in the thymus gland. The tumor weighed two and three-fourth pounds. The heart was not displaced.

From the nature of the fluid we should suspect malignant disease, but the acute onset of all the symptoms, together with the perfect health and good physical condition of the patient and the absence of any cachexia, would lead us to exclude that view.

A number of the cases on record were attended by pleural effusions, but they were all caused by some involvement of the pleura or lung tissue, or both, and in none was there sudden effusion. In not any of the cases was the effusion so marked as to be the cause for seeking relief. In searching the literature I found but one case that might be a parallel one. In the early part of the eighteenth century Boerhaave reported "a case of sudden and terrible death." On post-mortem examination a saponaceous tumor was found in the anterior mediastinum, and there was considerable effusion in the right pleural cavity.

As the post-mortem examination in my case did not reveal any cause for the effusion, I hope the discussion will bring forth some plausible explanation. My opinion is that the sudden change of position disturbed the relation of the tumor to the large vessels, causing the calibre of one or more of them to become diminished or obliterated for a time, thus giving rise to the effusion.

1333 FRANKLIN STREET, PHILADELPHIA.

Advances in Skiagraphy.—Dr. Arthur W. Goodspeed, of the University of Pennsylvania, has succeeded in obtaining a skiagraph of the upper portion of the trunk of his own body, as well as the lower part, showing the entire pelvis, the hip-joints, and a portion of the thigh bones, after an exposure of forty-five minutes. The result indicates that less time would have sufficed for the purpose. The tube used by Dr. Goodspeed is of his own design, and consists of a four-inch bulb with a branch on either side through which are introduced the electrodes, each of which is covered with blue enamel. One electrode consists of an aluminium disc, which is placed at one end of the tube, and the other terminates in a platinum disc, about one inch in diameter, which is placed at the centre of the tube and at an angle of forty-five degrees to the first disc. The tube is exhausted to about one-millionth of an atmosphere. A Ruhmkorff coil, with a ten-inch spark, is used, the primary current being broken two thousand times a minute by a motor. Dr. Goodspeed has undertaken to produce a series of pictures that shall show the normal condition of the bones of the human body in a state of health, and that shall serve as a means of comparison with abnormal or diseased conditions.

Clinical Department.

LOCAL APPLICATION OF TERCHLORIDE OF ANTIMONY IN A CASE OF EPITHELIOMA OF THE FACE.

By JOHN O. PALMER, M.D.,

AUBURN, N. Y.

ON November 26, 1895, the writer found himself confronted by an epithelioma covering an irregular oval space about two and a half inches by three and a half inches, extending from the tragus of the left ear to the outer canthus of the corresponding eye.

The edges of this ulcer were very much elevated and angry in appearance, and the whole surface was discharging an offensive purulent secretion, and at times bleeding freely.

In view of the extreme age of my patient (a married lady, eighty-one years of age, and the mother of a large family) and her enfeebled condition, the knife seemed to be out of the question. I therefore decided to give the case such benefit as might accrue from some form of escharotic.

Having seen excellent results in the hands of Dr. Carter S. Cole, of New York City, in similar cases by the use of the terchloride of antimony, I began its use on the above date.

After thoroughly cleansing the entire surface of its secretion and washing it with bichloride of mercury, 1 to 1,000, this powerful solution was applied over an area of about one-half the sore, including that section adjacent to the eye, as it seemed to be making most rapid inroads at this point and involving the most important tissue. The application was thus limited, as to have covered a larger surface would have invited too severe a shock in so weak a subject.

The action of the escharotic on the diseased tissue (which alone it attacks) formed a good crust, and the reaction was as good as could be expected, although the pain was considerable.

The subsequent secretion from the uncovered part of the sore was very offensive, and, while it loosened and carried away some of the crust, there was a fairly good cover left on perhaps one-third of the ulcer.

The dressing following this and all subsequent applications was two-per-cent. carbolic acid on sterilized gauze, and this was covered by rubber protective tissue. Also one-quarter of a grain of morphine sulphate and hot whiskey sling were exhibited.

On November 29th, third day, another application of the antimony was made over sufficient space to leave a good crust over the entire upper one-half. The shock at this time was rather worse, and there followed an extensive swelling. Salines and diuretics reduced this in a few days and she rallied remarkably well, so that on December 4th I was enabled to cover the entire sore.

This time I stimulated thoroughly and applied a solution of cocaine for ten minutes previous to the treatment. The secretion loosened a little of the lower part of the crust, and the swelling completely closed her eyes and caused much distress and apprehension. She also developed a temperature of 101° F. and a pulse of 115.

This condition yielded, however, to eliminative treatment and quinine, and she went on to a good reaction. The secretion loosened and brought away the crust pretty freely, and by December 20th it was all off and the sore began to look more auspicious, although the ulcerous surface was but little more than half its original size.

On December 22d after a hypodermic of morphine sulphate, one-fourth grain, with atropine sulphate,

one-seventy-fifth grain, and free stimulation, the antimony was again applied over the entire surface. There followed no untoward symptom other than a severe conjunctivitis, which was controlled by cocaine and boric acid in camphor water.

By the 28th the crust was all gone, the discharge was nil, the pain had entirely disappeared, the disease was conquered, and a healthy healing surface of about one inch by one and a half inches was all that remained to mark the site of the original epithelioma.

I regard this as a thoroughly satisfactory result of this recently revived treatment of these malignant affections of the face.

The writer desires to make acknowledgment to Dr. Carter S. Cole, with whom he had correspondence during the course of the treatment.

My apology for so full detail in this report is that there was about as much to contend with as was possible to conceive, in the age and feeble condition of the patient, together with the size and location of the sore. If I may have encouraged the profession to boldly attack this class of cases, I shall feel rewarded for my efforts.

A CASE OF ELECTRICAL CHOREA.¹

By AUGUSTUS A. ESHNER, M.D.,

PROFESSOR OF CLINICAL MEDICINE IN THE PHILADELPHIA POLYCLINIC,
PHYSICIAN TO THE PHILADELPHIA HOSPITAL.

THE case of electrical chorea that I shall herewith report does not belong to the type of disease described by Dubini in 1846.²

It represents rather a form of myoclonus in which the contractions occur at irregular intervals and are shock-like in character, resembling those induced by the interrupted electric current. These peculiarities seem to distinguish the affection from the ordinary type of chorea, and there is nothing to suggest an hysterical origin. Of the thirty-eight cases reported by Dubini thirty-six proved fatal, but no appreciable lesions were found after death. Treatment seemed to be without avail. Young people between the ages of seven and twenty years especially were affected. Fright was believed to be the usual cause. Among the premonitory symptoms were sleeplessness, anorexia, and prostration. The attack proper set in with rhythmic, shock-like contractions, usually in a given case of the same character throughout and involving the same muscles. The movements ceased during sleep. As the case progressed the involvement became more extensive, and finally the parts affected were paralyzed. The paroxysms lasted from four to ten minutes each and were repeated several times daily. The usual duration of the attack was from one to five or six months.

The case that I have to report is in a patient under observation at the Nervous Dispensary of Howard Hospital, in the service of Dr. Lewis Brinton, to whose kindness I am indebted for the privilege of making this report. It occurs in a woman, twenty-three years old, without special neurotic family history; though there is a marked history of tuberculosis on the side of the father. The patient herself has been married, but does not live with her husband, and has been delivered of a six-months dead-born child. She has had the jerking movements which she presents since the age of seven years. These are of a peculiar shock-like character and involve especially the arms and forearms, though movements can also be observed at times in the face. They are variable in intensity, ceasing entirely during sleep and being less

¹ Report read before the Philadelphia Neurological Society, April 27, 1896.

² Ann. Univ. di Med., cxvii., p. 5.

pronounced when the patient is calm and quiet; they are also absent when the patient is walking, although a jerk occurs with the first step. The patient can knit and write with facility, jerking very little in the performance of these acts. She thinks the movements may have been rather less pronounced during such attacks of illness as she may have suffered from. The knee-jerks are exaggerated, and feeble ankle-clonus can be elicited on the left. The onset of the movements followed the fright of being locked in a wardrobe. The heart and lungs present no abnormality.

I think this case may be safely called one of chorea, though not of true Sydenham or of Dubini type. There is reason to believe that chorea, as seen in its various forms, is not a single affection and that all cases do not have a uniform pathology. We are able now to distinguish Sydenham, Huntington, Dubini, hysterical, and post-hemiplegic varieties, and the future may perhaps bring us knowledge of others. The character of the symptoms suggests that the seat of the disease is the cerebral cortex, and the clinical course of cases would indicate that the disturbance may be functional (habit-chorea), nutritional (Sydenham's chorea, hysterical chorea), structural (Huntington's chorea), or organic (post-hemiplegic chorea).

REPORT OF A CASE OF BURSITIS.

BY H. M. GARDNER, M.D.

ATHOL, MASS.

MRS. R—, fifty years of age; health good until July, 1895, when her knee was injured by the breaking of a jack-screw. A physician was called, and subsequently three others; but all treatment was of no avail. The knee grew worse and pain was constant. I was called to see the patient and found her unable to move without crutches, which she had used three months. Her leg was œdematous from the toes to the trunk, and her general condition was poor. I applied a rubber bandage the whole length of the limb, and prescribed a tonic. This was Wednesday. Friday of the same week I called again and found the leg one mass of vesicles, with a marked diminution in the swelling. I opened the vesicles, washed the leg antiseptically, dusted with iodoform, and encased the whole limb in a plaster bandage. I told the patient I would return in ten days, but did not until eighteen days had passed, when to my surprise my patient met me at the door. She had removed the plaster the day before and complete recovery had taken place. In a case of eight months' standing this result may seem remarkable, nevertheless it is true. I never treated a similar case in this way, but shall any others that I may have.

HORSE SERUM IN CONSUMPTION — REPORT OF RECOVERIES AND IMPROVEMENTS.

BY J. A. DUNWODY, M.D.,

CRIPPLE CREEK, COL.

I WILL begin with my own individual case.

CASE I.—J. A. D—, male, white, aged thirty. On July 26, 1895, upon physical examination the upper two-thirds of the left lung was found to be infiltrated; numerous moist râles could be heard throughout this portion, and there was expectoration of a muco-purulent character, about two ounces during the twenty-four hours. Weight, one hundred and twenty-five pounds. Microscopic examination showed tubercle bacilli. Range of temperature was from 99° to 100° F., and this continued until August 2d, when I was attacked with acute pleurisy on the left side,

which confined me to my bed for ten days. The temperature ranged then from 100° to 102.5° F. for a week, after which time it fell to 99° to 100° F., until September 18th, when it became 98.5° F. The injections of serum were begun on July 26, 1895, with ten millimetres and rapidly increased to forty-five millimetres, and were then reduced to thirty millimetres, which quantity was maintained continuously, notwithstanding the attack of pleurisy, until December 24, 1895, at which time a small abscess was produced, owing to the want of proper care by the physician giving the injection. Weight at this time (December 24th) had increased to one hundred and forty-three pounds; the expectoration had nearly ceased, there not being enough for microscopical examination. Physical examination revealed the absence of all râles; there was clear vesicular respiration throughout the affected portion of the lung, though somewhat weak in character. The right lung was not affected at all. On March 24th I was attacked with la grippe, during which time my weight was reduced to one hundred and thirty-four pounds and cough returned for a short while, with loss of appetite, etc. On April 13th I resumed the daily injection of thirty millimetres of serum, with resulting increase of weight of two pounds and cessation of cough at this time, April 23d. I have used no other treatment at all—the injections of serum alone. This point in my case proves conclusively the great mistake of stopping the use of the serum too soon, or before the lung tissue has been restored to its full strength and vitality.

CASE II.—H. H—, white, female, aged four years, weight twenty-seven pounds. Date of examination, January 3, 1896. Left lung almost completely consolidated; no vesicular respiration; bronchophony quite distinct; cough quite distressing at times; range of temperature, 99° to 100° F. in afternoon. I began on January 3, 1896, with the injection of serum, four millimetres, and rapidly increased to twelve millimetres daily. The right lung showed no lesion. During the first six weeks of sero-therapy patient increased in weight four and a half pounds, and has maintained this weight (thirty-one and a half pounds) until the present time. Upon physical examination on April 8th, I find that there is some vesicular respiration throughout the affected lung. Cough has almost entirely ceased. During the last three weeks the injections have been somewhat irregular, as the little patient lives two miles away from my office, and has had a mild attack of scarlet fever which has been quite prevalent where she lives.

CASE III.—Mr. S—, white, male, aged forty-six; weight, one hundred and thirty-five pounds. Date of examination, March 16, 1896. Left lung almost completely consolidated; no vesicular respiration, quite dull and flat upon percussion; small tuberculous ulcer upon the epiglottis and vocal cords, affecting the voice; expectoration about four ounces daily. Patient stated that he was first affected with tuberculosis in October, 1894. A daily injection of thirty millimetres of serum was begun immediately. There was considerable erythema in this case, which gradually disappeared, though the serum was given daily. On examination April 21st, I found that there had been wonderful improvement in the condition of the lung; there was already some slight vesicular respiration throughout the lung. Expectoration had diminished about one-half, or to two ounces in twenty-four hours. He had increased four pounds in weight. When this patient commenced the daily injections he could walk only a short distance without extreme fatigue. Now he states that he can walk at least half a mile without any discomfort at all.

CASE VI.—J. B—, male, white, aged twenty one. Date of examination, February 15, 1896. The patient

stated that he had had tuberculosis since the spring of 1893, and that his normal weight used to be one hundred and forty-three pounds. The left lung at the time of examination was in the same condition as in the preceding case: no vesicular respiration, dull and flat upon percussion. He weighed at that time one hundred and fifteen pounds, and was much emaciated. The patient is difficult to control, and comes only irregularly for injections. He has not gained in weight. There is evidence that he is addicted to masturbation. Upon examination on April 21st, I can find very little or no improvement in this case, and there is very little hope of his ever being relieved. (Such cases cannot be expected to recover by any mode of treatment short of the miraculous.)

I have given here a history of these cases sufficiently full, I trust, to enable the reader to form a judgment. I am thoroughly convinced that sero-therapy is in the line of right treatment, that will eventually rid the dread disease (tuberculosis) of all its terrors and its fatal record.

Progress of Medical Science.

Achillodynia.—From an editorial writer in the *Boston Medical and Surgical Journal* we learn that two years ago Albert described and named a condition of the foot characterized by pain on walking and standing, located at the insertion of the tendo Achillis, but disappearing in the sitting or lying positions. In addition to this, a small swelling is to be noticed, apparently due to the thickening at the insertion of the tendo Achillis. The swelling, which is as hard as the tendon, in some instances is slightly sensitive to the touch. It appears as if the bone itself is enlarged. Rössler reports nine cases of this affection, which he is inclined to consider the result of the inflammation of the bursa between the tendon at its insertion and the projection of the os calcis. In one of these cases only was there any evidence of presence of fluid in the bursa on palpation, but an experimental injection of fluid into this bursa upon a cadaver did not give clear evidence of fluctuation owing to the tenseness of the structures. Schüller found in two obstinate cases of this affection reddening and thickening of the walls of the bursa and synovial fluid, which was manifest on operation of the case. He demonstrated the existence of the bursa in a large number of cadavers. In one hundred and forty cadavers he found twenty-five bursæ; and in twenty cases of new-born children, synovial membrane was found in this region. In a number of investigations upon cadavers, Rössler found frequently thickening of the cartilage and hyperostosis of that portion of the os calcis which forms the anterior wall of the bursa, constituting a bursitis deformans, the result of chronic irritation similar in his opinion to the formation of callus. Weinlechner reports operating upon a case of this sort in a patient twenty-one years of age; the bursa was incised and curetted and a bony prominence chiselled off. The same affection has been described by Kirmisson as peritendinous arthritis, and is mentioned by Heinecke in his work on the "Anatomy and Pathology of the Tendon Sheaths and Bursa." The affection is apparently in some instances induced by injury. Cases have been cited where the origin is attributed to influenza and to gonorrhœa. In one case apparently the affection was rheumatic. Treatment can be operative or conservative; the latter includes the application of wet sponges with compression and later massage; the former—incision into the bursa, curetting the bursal wall, and removal of projecting bone. Under the

name of "subtendinous exostosis," Dr. E. G. Brackett reported a case of an affection similar to that described by Rössler. A few of these cases had been observed by Brackett independently of the work of the German observers. In the one operated upon six months ago and recently reported, the affection was considered by the patient to have resulted from a sudden strain in jumping, which was followed by a swelling on the outside of the tendo Achillis; this was tender to the touch and caused pain in walking. The swelling was on either side of and between the tendon, but was greater on the outer than on the inner side; and on account of the resulting disability the patient was obliged to walk upon crutches for a year and a half. Any attempt to walk without crutches was followed by an increase in the swelling and sensitiveness at the side of the insertion of the tendon. A hard swelling was felt on the back of the heel, with slight puffiness and fluctuation on each side of the tendon. On cutting down upon the swelling a hard bony growth was discovered on the upper portion of the os calcis; the tendon was split, and the growth was found to occupy the upper portion of the exterior surface of the os calcis, and presented a sharp projection under the tendon and slightly above its insertion, in such a position that on every step in walking the tendon would be stretched over a sharp projection of bone. The tumor was removed by a chisel; the patient made a complete recovery. A subsequent case has since been observed by Dr. Goldthwait; and the probabilities are that the affection is more common than has been supposed, but has been overlooked from the fact that attention has not been called to the subject.

Strapping the Chest in Phthisis.—Dr. Tidley (*British Medical Journal*) suggests the following advantages: 1. In early phthisis (catarrhal stage), to give comparative rest and relaxation to the affected lung tissue. 2. In the stage of consolidation, to secure the same results, thereby limiting the risk of extension, and to promote elimination of the disease products by improving the circulation in and about the diseased area, and to facilitate expectoration. 3. In the stage of cavitation, to promote closing of cavities by directing healthy lung to encroach on the diseased area, instead of relying on natural processes of cicatrization. 4. Diminished tendency to hemorrhage by reduced tension on vessels and cicatricial traction on vessel walls. 5. The ultimate object is to obtain a smaller thoracic cavity filled with healthy lung, instead of an enlarged thoracic cavity partly filled with diseased lung.

Cold Baths in Delirium Tremens.—Dr. Letulle speaks of the various drugs that have been used and recommends cold baths, not a simple douche, but immersion of the whole body in water at the temperature of 64.4° F. The head should be cooled by large waves of water. The bath should last eight, twelve, or fifteen minutes according to the reaction of the patient. The baths may be repeated every two or three hours. It is concluded that these baths possess a sedative and calming action upon these cases.—*La Presse Médicale*, 1896, No. 4, p. 20.

Whooping-Cough.—Dr. Fisher concludes from the results he has obtained in the quinine treatment of pertussis that it is the best remedy for whooping cough at present known for the following reasons: (1) It diminishes the number of attacks essentially in five days at the latest. (2) It reduces even the most vehement whooping-cough to a mild bronchitis in from twelve to fifteen days. (3) It influences most favorably a possibly existing broncho-pneumonia. (4) It often stimulates the appetite.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, July 11, 1896.

LATENT AND LARVAL TUBERCULOSIS.

As certain conditions are necessary for the lodgment and propagation of the tubercle bacillus in the human body, an intelligent prophylaxis will look to the maintenance of the normal mechanism by which such invasion is ordinarily repelled and by which also the process of spontaneous recovery from the developed disease is brought about. From the same point of view, it is obvious that success in the treatment of tuberculosis depends largely upon its early recognition. Here, however, we encounter a serious difficulty, as the disease may develop without giving rise for a time to appreciable manifestations, and these may not appear until the morbid process has made considerable progress.

It is a well-known fact, long observed, that tuberculous lesions are often found after death when their existence during life had not attracted especial attention or had even escaped observation. So well established is this fact that the Germans have adopted an axiom that every one ultimately becomes infected with tuberculosis. The multiplication of the tubercle bacilli and the generation of toxins occasion only local effects until the intensity of the process has reached such a degree that the resulting products gain entrance into the circulation and thus give rise to constitutional manifestations.

Maragliano,¹ in an address recently delivered, discusses the question of latent and larval tuberculosis and offers a number of interesting and valuable considerations bearing upon that subject. When tuberculosis is present without subjective or objective symptoms, he goes on to say, the latency may pursue one of three courses: (*a*) It may persist indefinitely; (*b*) it may be limited in duration; or (*c*) it may be intermittent in occurrence. When the latency is persistent the infection is beyond the range of certain detection, the processes of auto-therapy or auto-serum-therapy sufficing to control the advance of the disease. Late in the history of the case there may be some impairment of resonance, in consequence of the presence of new-formed cicatricial connective tissue. When the latency is limited in duration, the infection—for a variable period not manifest—suddenly makes its appearance. In this group belong cases in which without previous symptoms hæmoptysis occurs; also those in which manifestations of tuberculosis make

their appearance in connection with some acute infectious process. The duration of this limited latency is variable and uncertain. The transition from latent to manifest tuberculosis may be viewed as an evidence of increased intensity of infection or of diminished bodily resistance, or perhaps a combination of the two. The developed disease may (*a*) progress, (*b*) remain stationary, or (*c*) subside, perhaps permanently, perhaps to recur.

Larval tuberculosis is that in which typical manifestations of infiltration are wanting, although other symptoms of the infection are present. This type of the disease may appear in one of two forms: (1) dystrophic, (2) typhoid. The first is characterized by progressive disturbance of nutrition. The patient gradually fails, anæmia develops, the heart becomes enfeebled and the pulse rapid, the appetite is lost and the digestion impaired, debility ensues and mental depression results. As a rule, there is an absence of fever, and physical signs may appear only late. The typhoid form of larval tuberculosis is from the beginning attended with fever, to which derangements of innervation are early added. The fever is at first intermittent, later becoming remittent or subcontinuous. The general strength may be maintained. Exacerbations closely resembling attacks of typhoid fever are repeated from time to time. In some cases both types of the disease may be present.

The manifestations of larval tuberculosis are to be attributed to intoxication with the products of bacterial activity and vary as one or other poison predominates. The symptoms of tuberculosis may be masked, whatever the localization of the lesion; but this is most often the case when the lungs and the lymphatic glands are involved.

The diagnosis of larval tuberculosis must be made by exclusion, the greatest care in observation being exercised. Tuberculosis of persistent latency is beyond recognition; if the latency is intermittent the history of the case is of the utmost diagnostic significance. In some cases in which doubt exists after the exhaustion of all therapeutic resources, Maragliano suggests a study of the toxicity of the blood-serum. He has found that from three to five cubic centimetres of blood-serum from a patient suffering from tuberculous toxæmia for each kilogram of body weight is sufficient to cause death in rabbits. The best means, however, of detecting the existence of latent tuberculosis is the intelligent use of tuberculin injected beneath the skin. Some individuals will react to injections usually from one to three milligrams and never exceeding ten milligrams, with fever and physical signs such as râles at an apex, with harsh breathing, etc. Others will not react to this dosage, but after an injection of twenty-five milligrams will present swelling of lymphatic glands and localized signs in the lungs or other organ.

The existence of tuberculosis being thus established, the treatment will be general or general and specific. The first includes all measures capable of improving the general nutrition and increasing the bodily resistance. The last includes the judicious use of tuberculin or antitoxic serum.

¹ Berliner klinische Wochenschrift, 1896, Nos. 19 and 20.

ANTI-VIVISECTION EXTREMISM.

THE pernicious influence that may result from the utterances of certain well-meaning but misguided individuals, including medical men, is admirably illustrated by a circular recently issued by the American Anti-vivisection Society. In this remarkable communication an appeal is made to the public not to circulate stories about "alleged mad dogs, and the terrible results to human beings bitten by them. Such accounts frighten people into nervous disorders and cause brutal treatment of animals suspected of madness; and yet there is upon record a great mass of testimony from physicians asserting the extreme rarity of hydrophobia even in the dog, while many medical men of wide experience are of the opinion that if it develops in human beings at all, it is only on rare occasions. The condition of hysterical excitement described as 'hydrophobia' is merely a series of symptoms due usually to a dread of the disease, such dread being caused by realistic reports acting upon the imaginations of persons scratched or bitten by animals suspected of rabies." To this statement are added the opinions of a number of medical men, most of whom are not known as investigators or clinicians of wide modern experience, who contend for the non-existence of hydrophobia, because the disease has never been recognized by them. There are still some medical men who are unwilling to admit that hysteria is a genuine disease, apart from simulation, but if there is any great clinical truth that has of late received general professional acceptance it is that hysteria is a reality, just as much as typhoid fever or pneumonia. Those who deny that there is such a disorder as hydrophobia may as well deny that there is such a disease as hysteria. Perhaps, however, the scientific world is wrong and the dissenters are right. No doubt the anti-vivisectionists are as nearly right as they usually are. To a judicial mind it must seem the supremest folly to base a conclusion solely upon negative evidence and to deny the existence of that which has not come under one's personal observation. So long as there are some who oppose the bacillary doctrine of disease, so long will there be some who deny the existence of hydrophobia in man and rabies in animals. Conservative anti-vivisection is a legitimate agitation and will receive the support of all right-minded people, but a blind fanaticism will defeat its own ends. No cause can fail in the end that is based upon truth and none succeed promulgated upon error.

THE PATHOGENESIS OF ABDOMINAL FAT NECROSIS.

ONE of the most obscure conditions with which the clinician has to deal is that known as fat necrosis, many years ago observed by Ponfick in bone marrow and later described by his assistant Balser as occurring in the pancreas. The condition has since been frequently noted in association with pancreatic disease, especially hemorrhage, although it may occur independently. The white necrotic areas, of varying

size, have been shown by Langerhans to contain lime in combination with fatty acids.

Of the cause and mode of origin of this condition there is as yet little definite knowledge. It has been induced in the dog by injecting pancreatic extract into the fatty tissue, and in cats by ligation of the pancreas or its vessels and by transplantation of pancreatic tissue. In two cases Welch found the bacillus coli communis. Stockton in two cases found bacilli of varying size, some with square and some with rounded extremities.

The latest contribution to the pathology of this interesting subject is made by Ponfick,¹ who has succeeded in isolating from the fluid obtained from an area of subperitoneal hemorrhagic infiltration upon the posterior wall of the abdomen, in a fatal case of fat necrosis, a bacillus morphologically resembling both the bacterium coli commune and the typhoid bacillus, but differing from both of these in culture and in pathogenic properties. The organism is described as a fairly large bacillus, with rounded extremities, about two or three times as long as it is thick, and possessing pathogenic activity toward white mice and rabbits. It is capable of independent movement, stains readily with aniline colors, and does not liquefy gelatin. In cultures it proved to be a facultative anaerobe. The patient was a corpulent man, forty-three years old, who died in the course of a few days with symptoms of intestinal obstruction.

News of the Week.

Obituary Notes.—DR. J. B. TAYLOR died on June 16th, at San Angelo, Tex. Some weeks ago he was thrown from his horse and received a compound fracture of the arm, from which septicæmia developed. Dr. Taylor was born in New York fifty years ago, and practised here until he was obliged to remove to Texas on account of his health.—DR. AUGUSTUS S. KIDDER died in this city on July 5th, of pulmonary tuberculosis. He was born in New Hampshire in 1840, was graduated from Dartmouth College in 1860, and later from the Philadelphia Dental College. Immediately upon graduation he came to this city, where he practised dentistry to within a short time before his death.—DR. JAMES D. BROWDER died on his plantation at Gallion, Hale County, Ala., on June 27th. He was a graduate of Jefferson Medical College and engaged for a time in the practice of medicine in Philadelphia.

The Third International Congress of Dermatology.—At this congress, which, as already announced, will be held in London, from August 4th to 8th, there will be a museum of drawings, casts, models, naked-eye preparations, microscopic specimens, works, and atlases pertaining to diseases of the skin. There will also be an exhibition of clinical cases and demonstrations of the same, at 9 A.M. and 2 P.M. of August 5th, 6th, and 7th, and at 9 A.M. of August 8th. Any one having anything to contribute to this department is requested to address Dr. James Galloway, 21 Queen

¹ Berliner klinische Wochenschrift, 1896, No. 17, p. 865.

Anne Street, Cavendish Square, W., London. There will also be an exhibition of cultures and microscopical preparations of organisms connected with the skin and its diseases. Any communications in regard to this department should be addressed to H. G. Plimmer, Esq., Wunderbau, Sydenham, London. The social side of the congress will be: 1st, an informal reception at the International Hall, Piccadilly Circus, on August 3d, from 9 to 12 P.M.; 2d, a reception by the lord mayor and lady mayoress, at the Mansion House, on August 5th, from 9 to 11 P.M.; 3d, a dinner to the foreign members, at the Hotel Cecil, on August 7th. It is advised that foreigners should arrive in London not later than Sunday, August 2d, as Monday, August 3d, is a public holiday.

Dr. George E. de Schweinitz has been elected professor of ophthalmology in Jefferson Medical College, in succession to Dr. William Thomson, resigned; Drs. D. Braden Kyle and William S. Jones, clinical professors of laryngology; and Dr. H. F. Harris, assistant professor of pathology and bacteriology.

The Chalfont Epileptic Colony.—A home for twenty women has been added to the epileptic colony at Chalfont, England, where formerly there has been provision for men only.

The Marine Hospital, at New Orleans, has recently been sold by the federal government to the city for \$25,700. It was built many years ago at a cost, including the purchase of the ground, of between \$600,000 and \$700,000, and was never occupied.

Robbed and then Imprisoned.—A physician in this city suffered recently from the depredations of an office thief, and in the kindness of his heart called upon his colleagues in the neighborhood to warn them. One of the latter, so far from being grateful for the warning, took the doctor himself for a thief, and had him arrested as a suspicious character.

The French Surgical Association will hold its tenth annual meeting in Paris during the week ending October 24, 1896, under the presidency of Professor Terrier. The two subjects for set discussion are "The Surgical Treatment of Clubfoot," to be opened by M. Forgue, of Montpellier, and "The Treatment of Prolapse of the Genital Organs," to be opened by M. Bouilly, of Paris. The secretary-general of the association is M. Lucien Picqué, No. 8 Rue de l'Isly, Paris.

Lepers in Paris.—Dr. Hallopeau, writing to the *Matin*, says that there are over one hundred lepers living in Paris without any attempt at isolation, most of them having come from other countries for medical treatment. Recently one was found on the street and taken to the Hôpital St. Louis, where there are now twelve under treatment.

To Drive Away Flies.—Dr. H. S. Baketel, of Derry, N. H., writes: "Many practitioners of medicine among the poorer classes are greatly annoyed by flies in the sick-room. The annoyance to the patient is doubly great. Such, at least, was my experience not

long since on New York's great east side. An excellent safeguard against these pests is the sweet-pea flower. The *Lathyrus maritimus*, the purple variety, grows near the seacoast from New Jersey around to Oregon, and beside the coasts of the Great Lakes. The *Lathyrus ochroleucus* is found on the hillsides from New England to Minnesota, and even further West. It is distinguished by its small, yellowish-white flower. Either of these varieties can be grown in the sick-room, and the sweet odor emanated seems very offensive to the ordinary house fly."

Pathological Society of Philadelphia.—A stated meeting of the Pathological Society of Philadelphia was held on the evening of June 11th, the president, Dr. J. H. Musser, in the chair. Dr. J. Dutton Steele presented specimens of verrucose mitral endocarditis, aneurism of the abdominal aorta, right-sided sclerotic endocarditis, and a greatly dilated heart, giving rise during life to symptoms suggestive of both aneurism of the arch of the aorta and mediastinal tumor, such as dilatation of the veins of the chest: œdema, at first unilateral, but later becoming bilateral; and inequality of the pulses. Dr. F. A. Packard presented two specimens of right-sided endocarditis. Dr. D. Riesman exhibited a specimen of fibrous pericarditis, with hypertrophy and dilatation of the heart and partially patulous ductus arteriosus, from a girl with a history of rheumatism followed by chorea. Dr. Joseph Sailer showed the heart of an infant a few days old, exhibiting right-sided malignant endocarditis, and made a report of three cases of chronic endocarditis in association with pulmonary tuberculosis. Dr. Alfred Stengel presented a series of stomachs from cases of pernicious anemia and exhibiting atrophy of the gastric tubules, one of which was an extremely small viscus, not so large as an ordinary fist and with greatly thickened walls, from an adult woman. Dr. Stengel also showed intensely anthracotic lungs from the body of a coal-miner. Dr. A. O. J. Kelly presented a specimen of carcinoma of the stomach.

Methodist Hospital of Philadelphia.—Dr. Joseph P. Tunis has been elected visiting surgeon to the Methodist Hospital of Philadelphia, succeeding Dr. H. R. Wharton, who has resigned.

Dr. A. C. Abbott, hitherto first assistant, has been elected professor of hygiene in the University of Pennsylvania, in succession to Dr. John S. Billings, resigned.

The National Conference of State Boards of Health, recently held at Chicago, elected the following officers: *President*, Dr. C. A. Ruggles, of Stockton, Cal.; *Vice-President*, Dr. Benjamin Lee, of Philadelphia; *Secretary and Treasurer*, Dr. C. O. Probst, of Columbus, O.

Spanish Army Surgeons.—The Spanish government has raised the age limit for those desiring to enter the army medical service from thirty to forty years, on condition that those so admitted shall serve in Cuba until the close of the war.

American Physicians Honored in China.—Dr. Eli Barr Landis, ex-resident physician of the Lancaster County Hospital and Insane Asylum, has recently received the Order of the Double Dragon from the Emperor of China in recognition of services rendered by him during the war between China and Japan. The same distinction had already been bestowed on another American medical missionary, Dr. B. C. Atterbury, for work in connection with the Red Cross Society in the late war.

The Second International Congress of Gynecology and Obstetrics will be held in Geneva, Switzerland, from August 31st to September 5th inclusive. The sessions of the congress will be held in the grand hall of the university. The following are the subjects for the set discussions and the names of those who will open the same:

Gynecology: 1. "Treatment of Pelvic Suppurations." Referees.—Drs. Bouilly, Paris; Kelly, Baltimore; Zweifel, Leipzig. 2. "Surgical Treatment of Uterine Retro-Deviations." Referees.—Drs. Küstner, Breslau; Pozzi, Paris; Polk, New York. 3. "What Method of Closing the Abdomen Presents the Best Guarantee against Abscesses, Eventrations, and Hernias?" Referee.—Dr. Granville-Bantock, London.

Obstetrics: 1. "Relative Frequency and Most Common Forms of Pelvic Contractions in Different Races, Groups of Countries, or Continents." Referees.—Drs. F. Barnes, London; Dohrn, Königsberg; Fochier, Lyons; Kufferath, Brussels; Jentzer, Geneva; Lusk, New York; Rein, St. Petersburg; Pawlik, Prague; Pestalozza, Pavia; Treub, Leyden. 2. "Treatment of Eclampsia." Referees.—Drs. Charles, Brussels; Charpentier, Paris; Halbertsma, Utrecht; Löhlein, Giessen; Mangiagalli, Milan-Pavia; Parvin, Philadelphia; Smyly, Dublin.

The official languages of the congress will be English, French, and German. An exposition of gynecological and obstetrical instruments and appliances will be held during the congress week. As the national exposition of Switzerland will be held at the same time as the congress, those intending to be present are advised to secure hotel accommodations in advance. Further information may be obtained by addressing the secretary-general for North America, Dr. Fernand Henrotin, 353 La Salle Avenue, Chicago, Ill.

International Congress of Criminal Anthropology.—The fourth International Congress of Criminal Anthropology will be held at Geneva on August 24th to 29th. M. Adrien Lachenal, president of the Swiss Confederation, is honorary president of the congress. Dr. Paul Ladame is president of the organizing committee.

The Right to Practise in England on an American Diploma.—An English court has recently decided that an American physician with a genuine diploma from a recognized medical school is at liberty to practise medicine in Great Britain, but must not assume any titles implying that he is a registered British practitioner. The case was that of an American who appended to his name the letters, "M.D., U. S.

A.," and the court held that there was no attempt to claim qualifications other than those implied. The Medical Defence Union, which undertook the prosecution, was condemned to pay costs amounting to about £800.

Unwelcome Newspaper Notoriety.—Dr. Warren L. Babcock, of the St. Lawrence State Hospital, writes: "The undersigned desires to disclaim any responsibility for the sensational reports which have been going the rounds of the New York newspapers during the past week regarding an alleged insanity cure. The article in the *Sunday Journal* of July 5th especially merits repudiation and condemnation. No interview was granted the reporter, the affixing of my signature at the end of the alleged interview was a bold forgery, and no original discovery has been made or new treatment adopted. The illustrations are wholly imaginary in every particular, instead of being reproductions from photographs. The work to which the sensational article crudely refers will be published in its proper place—a medical journal—as soon as the results of investigation will warrant."

Fees from Clergymen.—The question of accepting or demanding a fee for medical services rendered a clergyman has reached the stage of open discussion in Scotland. Dr. D. Campbell Black, of Glasgow, recently read a paper on the subject before a local medical society, in which he said that, while he believed that poverty and suffering would never appeal in vain to the worthy disciple of Hippocrates, he distinctly failed to see why, "because a man is a clergyman, he is entitled to sponge, particularly on a young and poor practitioner of medicine."

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending July 4, 1896: June 29th.—Surgeon I. G. Heneberger, detached from the marine rendezvous, New York, and ordered to the hospital, Widow's Island; Passed Assistant Surgeon E. S. Bogert, ordered to the New York Navy Yard, July 2d; Passed Assistant Surgeon T. C. Craig, detached from the New York navy yard, July 2d, and ordered to the marine rendezvous, New York. July 2d.—Passed Assistant Surgeon W. F. Arnold, detached from special duty in China and Japan and ordered to return home; Assistant Surgeon H. F. Parrish, ordered to the naval laboratory, New York City.

An Income Tax on Physicians.—Louisville, Ky., has imposed a license tax upon physicians, graded according to their income. In case the income is less than \$2,000 the annual license shall be \$10; \$2,000 and over and less than \$5,000, the license will be \$20; where the annual income is as much as \$5,000 but less than \$10,000, the license is \$40; all whose yearly business amounts to \$10,000 or over, shall pay a license of \$100. The *Louisville Medical Monthly* says that the medical societies of Louisville have appointed committees to confer with each other and take steps to test the legality of the law. A test case will be submitted to the court, and until this is done all physicians are requested to resist payment of the license.

Society Reports.

MEDICAL SOCIETY OF NEW JERSEY.

One Hundred and Thirtieth Annual Meeting, Held at Asbury Park, June 23 and 24, 1896.

WILLIAM ELMER, M.D., OF TRENTON, PRESIDENT.

Report of Committee on Arrangements.—DR. HENRY MITCHELL, in presenting this report, stated that Asbury Park was free from certain noises which were such a nuisance in other cities. By ordinance peddlers and hucksters were not allowed to cry their wares in the streets. An ordinance had also been recently passed, requiring that all milkmen obtain a license, which they could do only on showing that the milk was pure, clean, from healthy cows properly kept. (Before their departure the delegates became convinced that this ordinance had not yet been fully complied with.) Another interesting feature of Asbury Park was that it kept a record book of all hotels and houses receiving summer visitors, giving all the facts relating to their sanitary condition—cellar area, ventilation, water supply, diseases which had occurred in them, etc. All interested could avail themselves of this information. The society was extended a warm welcome to this healthful seaside resort.

Permanent Delegates.—All of the permanent delegates proposed by the district societies were elected.

DR. ALFRED MERCER read his report as treasurer, which showed a balance of over thirty-five hundred dollars.

DR. E. L. B. GODFREY, corresponding secretary, in his report read some communications, one from DR. STERNBERG, relating to vivisection, and DR. DANIEL STORCK offered a resolution against the vivisection bill before Congress relating to the District of Columbia. The resolution passed through the hands of a committee and was then adopted unanimously.

Honorary Members.—Dr. A. Jacobi, of New York, and Dr. V. M. D. Marcy, of Cape May, were elected honorary members.

Purulent Conjunctivitis.—DR. W. B. JOHNSON, in the absence of the chairman of the committee, Dr. Kipp, read the report of the committee appointed last year to inquire whether the methods for the prevention of conjunctivitis of the new-born in hospitals accomplished what was claimed for them by their respective authors, and if so, to recommend that which, in their opinion, was best adapted for use in private practice. Personal observation, interview with physicians in large lying-in hospitals, and study of the literature of the subject had forced upon them the conviction that the development of purulent conjunctivitis of the new-born could be prevented by disinfection of the eye, and that the method recommended for this purpose by Professor Credé, of Leipsic, accomplished all that was claimed for it by its distinguished author. It was suggested that the society request the State board of health to publish Credé's method in the form of a circular and distribute it freely, and that the State board of medical examiners do not grant a license to practise midwifery to persons not familiar with this method. The Credé method consisted in carefully dropping upon the cornea one or two drops of a two-per-cent. solution of nitrate of silver. It should be applied in all cases just after or before cleansing the child.

DR. P. A. HARRIS made some remarks on the resolution to adopt the report, which was done.

Bovine Tuberculosis.—In the absence of Dr. Stickler, chairman of the committee, DR. YOUNG presented a brief report, stating that the subject had not been brought before the committee of the last legislature.

which was adverse, but the prospect for the future was more hopeful. The committee was continued.

Health of New Jersey.—DR. H. W. ELMER, chairman of the standing committee, read a summary of reports from physicians throughout the State on the health of their respective sections. The State had been comparatively free from epidemics, but there had been considerable grippe.

In discussing the report, DR. E. L. B. GODFREY called attention to the diminished mortality rate from typhoid fever in Cooper Hospital, Camden, since the introduction of the Brandt bath treatment. The average stay of the patients in the hospital had been reduced from fifty-two to thirty-three days. On the average, the patients were out of danger by the fifteenth day.

Clinical Observations on Auto-Intoxication of Gastro-Intestinal Origin.—DR. PHILIP MARVEL, of Atlantic City, in a paper of some length on the subject of auto-intoxication, acknowledged our indebtedness to Bouchardt, gave a definition of auto-intoxication, spoke of the toxicity of the urine, bile, and other secretions, dwelt more especially upon the influence of overeating, and related several interesting cases of acute and subacute or chronic nature.

Whence the origin of these poisons? All toxic substances existing in the excretions must be produced by decomposition of animal or vegetable food received within the body, by fermentative action of bacteria, and disintegration and restoration of cell life within the body itself. In the maintenance of life there was constant repetition of the processes of building up and breaking down.

Atlantic City, being a pleasure resort, gave many examples of the effects of overeating. Among symptoms of acute auto-infection from undigested food were tympanites, burning sensation, eructation of gases, acid vomiting, diarrhœa, increased formation of sulphuretted hydrogen, stools of greenish color, cramps, vertigo, headache, lightness of head, etc. There might be cramps, coma, and death. In one of his acute cases the patient died the second day, and congenital absence of one kidney was found, but the one present was healthy.

Demonstration of Bassini's Operation.—DR. S. E. MILLIKEN, of New York, demonstrated this method by drawings. He was first to describe it in this country, in a paper published in the MEDICAL RECORD some years ago. Those who opposed it then had since adopted it, and to-day it was the operation almost universally performed. He used kangaroo tendon, burying the sutures, and found non-suppurative essential to success. The patient was kept abed three weeks; no truss was worn subsequently.

DR. DANIEL STORCK, of Camden, had had no failures with the Bassini method, while Dr. Milliken admitted that he had.

DR. BENJAMIN and DR. P. A. HARRIS also made some remarks on the paper.

The Relations of Physicians and Pharmacists.—At the last annual meeting a committee, co-operating with a committee from the New Jersey State Pharmaceutical Association, proposed a code of ethics for the guidance of physicians and pharmacists in their relations to one another. This proposed code had been sent out in circular form to the physicians of the State for suggestions, preparatory to action at this meeting. Although it had been adopted by the State Pharmaceutical Association, evidently it did not meet with the approval of the majority of physicians, for as soon as it had been read it was voted, before debate could take place upon its merits, that action be indefinitely postponed. Dr. Shephard remarked that we could not regulate the conduct of pharmacists. Later a resolution was adopted, assuring Dr. Henry

Coit, chairman of the committee, and its other members and the pharmacists, that no discourtesy had been meant by this action.

Revision of By-Laws.—DR. HENRY MITCHELL, chairman of the committee on the revision of by-laws, read the report, and with a few exceptions it was adopted as read. The proposition to require the nominating committee to report three names instead of one for third vice-president (who is always advanced to president) was rejected through fear the election should too often fall to Essex County, in which Newark is situated.

Annual Address of the President.—DR. WILLIAM ELMER, JR., of Trenton, chose for his address "The Relation of the Physician to Sanitary Science." The subject was treated in a scholarly and instructive way, and the necessity for sanitary observance was impressed from a moral, social, and economic, as well as physical point of view. He said the education of the masses was the real groundwork of the national health. Disease was directly antagonistic to their interests as wage earners, and tended to the degeneration of the race.

"Statistics of our large cities show that about one-half of all deaths occurring are in children under five years of age, and a large percentage of these deaths takes place during the heated term, being attributed to cholera infantum. This waste of life in its early period is unnatural, and it should be inquired into, and as far as practicable removed. Crowded, badly ventilated, and poorly drained apartments, vitiated food, milk supply, hereditary diseases, and want of maternal care are the principal factors in the death rate of the slums of cities. The law compelling vaccination should be rigidly enforced and a school record of it should be kept. The teachers should know the early symptoms of communicable diseases and take suitable measures for protection. School authorities, in connection with local boards of health, can do much toward decreasing the spread of contagious diseases. 'Educate the people,' is the watchword of sanitary science, and the schoolroom is the place for its beginning. Filtration of the water supply of our large cities is a matter of importance that cannot be overestimated. Filtration is of greater importance than the purity of the source. The process of filtration is now being planned for Cincinnati. That the result will greatly diminish the prevalence of typhoid fever and acute intestinal diseases is unquestioned, as is shown by the statistics of certain European cities.

"According to Rochard, the economic value of an individual is what he has cost his family, the community, or the State, for his living, development, and education until he reaches the age when he can restore it by his own labor. This valuation has been variously estimated by different investigators. Chadwick, of England, considers a laborer equal to a permanent deposit of about \$980. Farr gives about \$780 as the average of value of each human life. F. F. Smith places the loss to a community by a death from typhoid fever at \$2,000, and, with this as a basis, Professor Mason, of Rensselaer Polytechnic Institute of Troy, in a recently issued book, estimates the yearly loss to a city of one thousand inhabitants, where there are seventy-five deaths from typhoid fever (estimating ten cases to one death) as nearly \$200,000." A pure water supply would prevent all this.

Among other things referred to as evidence of advance in medical science, Dr. Elmer mentioned regulations regarding tuberculosis, quarantine against cholera and other infectious diseases, etc.

A vote of thanks was extended to the president for his able address.

Fibroid Tumors of the Uterus Obstructing Labor; Their Subsequent Disappearance.—DR. GEORGE

H. BALLERAY read a paper, giving the histories of three cases of large fibroids of the uterus which had disappeared after labor. They had caused marked obstruction during labor. Other cases were cited in which such tumors had disappeared during or after pregnancy, the reason for which was not known. He would try to deliver by version, but should elytrotomy or Cæsarean section be demanded, he would certainly choose the latter.

DRS. W. B. JOHNSON, BENJAMIN, J. W. S. GOULEY, P. A. HARRIS, A. M. COOPER, and CURT discussed the paper. Dr. Gouley would explain the disappearance of such tumors after or during pregnancy on the belief that they were myomata, not fibromata; that they were composed of tissue like the uterine muscle, and with these underwent involution after labor, or became merged with them and flattened out during growth of pregnancy.

Princeton Laboratory and Bacteriological Diagnosis.—DR. M. RAVENEL, of Princeton Laboratory, spoke of the work being done in the bacteriological and microscopical lines in that laboratory, and showed cultures of bacilli of diphtheria, tuberculosis, etc., and microscopical slides. Last winter the legislature passed a bill providing for a State appropriation to enable this laboratory to make examinations of cultures and specimens sent them by physicians free, but it was vetoed by the governor for economical reasons. The society adopted resolutions requesting that such a bill be made the law, and a committee of three was appointed to appear before the committee of the legislature.

Medical Directory.—DR. H. R. BALDWIN said he had received a communication from Dr. Daniel Lewis, editor of the "Medical Directory of New York," in which he wrote that on receipt of one hundred subscriptions at one dollar each from New Jersey physicians, he would add the office hours of physicians residing in that State.

Is the Therapy of Antitoxin, Nuclein, and Thyroid Extracts so Fully Established as to Receive the Endorsement of the Profession?—This was the rather cumbersome title of a discussion presented at the last annual meeting. It was opened with a paper by DR. ALEXANDER McALISTER, who had devoted most of his attention to the antitoxin treatment of diphtheria.

Since January, 1895, he had treated forty-five cases of diphtheria with antitoxin, most of them in hospitals at Camden; only three had died—one of paralysis of the heart, one had rheumatic complications, one died of sepsis. There was a mild degree of diphtheritic paralysis in eleven, all recovering. The duration of the disease was shortened, urgent symptoms were quickly relieved, the results were most gratifying. Antitoxin was of marvellous value in laryngeal cases.

Dr. McAlister had immunized twenty-one cases. Two of these afterward had mild diphtheria. Dr. L. Emmet Holt, he said, regarded the evidence as most overwhelmingly in favor of the use of antitoxin. Statistics were then quoted, most of which are probably known to the readers of the MEDICAL RECORD. Dr. McAlister gave no personal experience with nuclein solution and thyroid extract.

DR. BARKER, of Trenton, related one case which would indicate the necessity for some caution in the use of antitoxin. He had employed nuclein solution to advantage in a case of Pott's disease of the spine and some other cases in children.

DR. W. B. JOHNSON had been called to intubate in about one hundred cases of diphtheria, and in about twenty of these cases the physicians had used antitoxin. Out of the twenty about fifteen had recovered, or seventy-five per cent.; whereas out of the whole one hundred cases only about thirty-eight per cent. had

recovered—more than twice as many recovering with antitoxin than without.

DR. DELAND, of Philadelphia, after stating the case in a judicial way, thought it must be admitted that there was in all parts of the world a decrease in the death rate from diphtheria under antitoxin treatment, and that, when administered within twenty-four or forty-eight hours, the serum exercised a beneficial influence upon the disease.

Dr. Deland had obtained no results from thyroid extract in goitre, but in some cases of obesity it had given good results.

DR. R. C. NEWTON referred to the extremely favorable statistics for antitoxin collected by the American Pediatric Society.

DR. STOKES had collected the cases in which physicians had used antitoxin in Burlington County, sixty-eight cases, with eight deaths.

DR. TITUS said he had used it in sixteen cases, all recovering but one, which was moribund when treated.

DR. F. B. CANTWELL said they had almost ceased to dread diphtheritic croup in the St. Francis Hospital, Trenton, since the use of antitoxin.

DR. BENJAMIN had reviewed statistics of about twenty thousand cases of diphtheria, and claimed there had not been a decrease in the death rate. When charged that he had not himself used antitoxin, he replied that he was not justified in doing so, because he had had one hundred per cent. recoveries from other treatment.

DR. BISHOP, of New York, said they had found thyroid extract of no value in Graves' disease at the clinic for nervous diseases, College of Physicians and Surgeons.

Antisepsis and Antiseptics from the Standpoint of the General Practitioner.—DR. C. R. P. FISHER, third vice-president, selected this topic for his essay. He held that asepsis depending upon perfect cleanliness was impossible for the general practitioner, especially in country practice, and that attempts at cleanliness should be supplemented by antisepsis in cleansing the hands and instruments, the field of operation, and the external genitals in confinement cases. He was opposed to routine irrigation of the vagina before labor, or in the absence of special indication.

There was some discussion upon this paper by Drs. SILBERS, HARRIS, and others.

Chloroform Narcosis.—DR. FLOY McEWIN, of Newark, read a full and practical paper upon this subject, dwelling principally on the indications and contraindications for chloroform, preparation of the patient for anæsthesia, and the manner of exhibiting chloroform by inhalation. He emphasized the fact that the anæsthetizer must give his whole attention to the administration of the drug.

Officers.—*President*, Dr. T. J. Smith; *First Vice-President*, Dr. D. C. English; *Second Vice-President*, Dr. C. R. P. Fisher; *Third Vice-President*, Dr. A. M. Halsey; *Corresponding Secretary*, Dr. E. L. B. Godfrey; *Recording Secretary*, Dr. William Pierson; *Treasurer*, Dr. Archibald Mercer.

The next meeting will be held in Atlantic City, on the fourth Tuesday in June, 1897.

Epileptic Colony.—Before adjournment the society adopted a resolution asking State legislation in the establishing of an epileptic colony.

The Abscess of Hip-Joint Disease.—Dr. McCurdy says the general surgeon has as a first principle the excision of all abscesses no matter where found, while the orthopædic is so conservative that he never opens an abscess nor even aspirates. Between these extremes is the orthopædic surgeon who excises and cures if necessary, or leaves alone if the case is running a harmless course.

AMERICAN NEUROLOGICAL ASSOCIATION.

Twenty-Second Annual Meeting, Held at Philadelphia, Pa., on Wednesday, Thursday, and Friday, June 3, 4, and 5, 1896.

PRESIDENT, F. X. DERCUM, M.D., OF PHILADELPHIA.

First Day—Wednesday, June 3d.

President's Address.—The president, DR. F. X. DERCUM, of Philadelphia, delivered an address entitled "The Functions of the Neuron." He dwelt at great length upon the various views advanced by Nansen, and quoted several abstracts from this well-known author's work. Speaking of naked axis cylinders, Dr. Dercum stated that they were in all likelihood a physiological impossibility in the cerebrum, for were they numerous we could suppose nothing but a constant overflow of stimuli from one cell to another, and consequent inco-ordination not only of thought but also of action. This is the view advanced by Nansen. The speaker stated that the question had arisen in his mind as to whether the neuron was not an absolutely fixed morphological element, and whether it did not possess a certain, though perhaps limited, power of movement. Continuing, he said: "Realizing the practical value and the wide application of this idea, I have examined the literature to see whether a similar interpretation of nervous phenomena has occurred to others, and to gather such facts if any could be brought forward in its support. I found that this thought had occurred independently to three observers, one in Germany and two in France. Ramon Cajal, however, opposes the theory of the mobility of the neuron, and maintains, on the other hand, that the neuroglia cells possess a great deal of mobility. He points out, for instance, that the neuroglia cells of the cortex are at times stellate and at others much elongated. Their processes have numerous short arborescent and plumed collaterals. Two phases can be observed in them: first, a state of contraction, in which the cell body becomes augmented while the processes become shortened and the secondary branches disappear; and secondly, a state of relaxation, during which the processes of the neuroglia cells are again elongated. Ramon Cajal further maintains that the processes of the neuroglia cells in reality represent an insulating or non-conducting material, and that during the period of relaxation they penetrate between the arborizations of the nerve cells and their protoplasmic processes, and render difficult or impossible the passage of nerve currents. On the other hand, when the processes of neuroglia cells are retracted the various nerve-cell processes which they formerly separated from each other are now permitted to come into contact. To me it seems as though Ramon Cajal admits the very thing against which he contends.

"Turning our attention for the moment to the subject of hysteria, we will see what a flood of light may be cast upon this hitherto so obscure and mysterious subject. Take the simple example of an hysterical paralysis and see how easily it may be explained. The neurons of a certain area of the cortex, for instance, retract the terminal branches of the neuraxon to such an extent that the latter are no longer in contact or sufficiently near to the neurons in the spinal cord which supply the muscles of the paralyzed parts. When power is suddenly re-established in hysterically palsied limbs, it simply means that the terminal branches of the cortical neuraxon, previously contracted, are again extended so as to re-establish the proper relations with the spinal neurons. It would be interesting to follow out the ideas here brought forward in their application to the various phenomena presented by hysteria.

"Turning to hypnotism, we can see what a ready ex-

planation it affords for the phenomena presented: and leaving this field entirely, we can see what an enormous value this interpretation of cortical action is for normal mental phenomena, taking, for example, the familiar instance of sleep. Numerous other ideas also suggest themselves in relation with the view here advanced, but time will not permit of my further discussing it."

Acute Non-Suppurative Hemorrhagic Encephalitis.—DR. J. J. PUTNAM, of Boston, read a paper with this title. The reader first sketched the literature of the disease, which has been mainly contributed by the German writers, the latest of whom is Oppenheim, of Berlin. The principal symptom groups are: 1, That described by Wernicke, as due to hemorrhagic softening mainly confined to the neighborhood of the third ventricle; 2, that described by Strümpell and others, as attending more diffuse lesions of the hemispheres; 3, it is possible that the hemiplegia of children may be due to a similar lesion involving the cortex, as Strümpell formerly suggested, and certain acute spinal lesions may belong in a similar category. Oppenheim has reported a number of cases, showing that, however grave the symptoms of this disease may be, the outcome may be favorable. The reader's case was that of a young boy who was attacked suddenly, two weeks after having been ill with the mumps, with paralysis of motion of both eyes and lids, deafness, coma, impairment of swallowing, right hemiparesis, and double optic neuritis. At the end of three months, however, he had recovered, except for slight double vision and slight impairment of hearing and eyesight, and except that ever since the illness he had been subject to epileptiform attacks of short duration. These attacks are gradually becoming less frequent. Reference was also made to another case reported by the reader in 1892, in which, besides other serious cerebral symptoms, including double optic neuritis, temporary loss of hearing had also occurred. The cases reported by Oppenheim were given in outline and the interesting fact noted that his patients, like the one here referred to, were mainly children. An analysis of these reported cases was also presented.

DR. L. C. GRAY, of New York, asked if any of these cases had retraction of the neck.

DR. PUTNAM answered that he was not certain as to its presence in his own cases, but it was present in the other reported cases.

DR. GRAY thought that the best macroscopical description of hemorrhagic encephalitis had been given by Flam some years ago. All cases seen by him (Gray) had proved fatal. In many instances the diagnosis was attended with extreme difficulty. He had generally been willing to diagnose these cases as meningitis.

DR. JOSEPH COLLINS, of New York, had observed a case of hemorrhagic encephalitis, with autopsy, which corresponded with the description given by Oppenheim. He read the report of the autopsy, which showed old leptomenigitis, hemorrhagic encephalitis, and a pachymenigitis hemorrhagica. There was no case on record in which these three conditions have been found associated.

DR. B. SACHS, of New York, said that the recognition of this form of cerebral disease showed a distinct advance in neurology. He had observed four cases. Two patients recovered and two died. In one case there was some doubt as to whether it was meningitis or not, as there was slight retraction of the neck but no positive coma. He looked upon it as a milder disease than basilar meningitis. In one of the patients who recovered, the cerebral symptoms appeared simultaneously with the fever. The former lasted four days, leaving the patient with slight ptosis and paresis of the external rectus.

DR. GRAY asked if fatal cases have shown more violent symptoms than those that recovered.

DR. PUTNAM replied that in some of the more violent cases the patients recovered. In general, the rapid development of severe coma is considered an unfavorable sign. It is frequently quite difficult to distinguish this condition from meningitis. He believes that the severity of the symptoms depends on the amount of poison absorbed into the circulation. We do not yet know the exact significance of retraction of the neck, which is a very unreliable diagnostic sign. In one of his own cases of influenza with symptoms of encephalitis occurring in an elderly person, the brain was found only oedematous. Sometimes changes are unrecognizable with the naked eye.

Cerebral Complications of Reynaud's Disease.—

This was the title of a paper by DR. WILLIAM OSLER, of Baltimore. After referring to the frequency with which Reynaud's disease is met with in forms of insanity, he said that in a few cases cerebral manifestations, due apparently to vascular changes similar to those which develop in the peripheral parts, had been described. In the case of a man in his wards, already reported in 1891 by Dr. H. M. Thomas, in which epileptic attacks occurred in the winter months only, in connection with local asphyxia and superficial necrosis of the ears, the patient had also hæmoglobinuria. In another case, that of a woman aged fifty-two, during a period of six years, local syncope and asphyxia occurred at intervals in the fingers and hand of the right side, sometimes with aphasia, and on several occasions with transient paralysis of the right arm and leg. In the final attack the patient died with gangrene of the right hand and arm. The case of Weiss is believed to be the only other instance in which aphasia complicated the disease. In a third patient "falling attacks" of an indefinite character occurred in a young girl, with local asphyxia of the legs between the knees and ankles.

DR. RIGGS asked Dr. Osler how often he had seen death follow this disease.

DR. OSLER answered that it was rarely fatal. This was the second fatal case with which he was familiar. The literature, however, indicated a number of fatal cases. He considered the complications as having no direct relation with the disease. The associated conditions were rarely serious.

Tumor of the Thalamus.—DR. WALTER CHANNING, of Boston, read a paper with this title. The patient was an unmarried woman of good heredity, and by occupation a school teacher. She was of an active, nervous temperament, and the subject of hay fever and asthma until the spring of 1895, when she was under the care of a so-called "hay-fever specialist" and escaped the usual attack. Before admission to the hospital, November 29, 1895, she had been for some weeks mildly exhilarated and extravagant in her ideas, but not enough so to interfere with her work until the 22d. The only physical symptoms she had complained of were headache and insomnia. Her disease was diagnosed by an alienist of experience as mild acute mania when she came to the hospital. Since her death her friends have stated that she had weakness of the left arm before leaving them, but nothing was said of this when she entered. She was mildly exhilarated, with expansive delusions and hallucinations of taste and smell. She was unable to stand because of weakness in the left leg, and her left arm was weaker than the right, there being no power to move it above the elbow. Headache, not severe or localized, existed. There was little nausea. The pupils were equal in size and reacted to light. The eyes did not follow the finger. There was no ophthalmoscopic examination. The weakness in the left side was not so marked at the beginning as to attract special attention. It was

later that its significance became apparent. Patella reflex slightly exaggerated and alike on both sides; plantar reflex moderate; urine: color normal, reaction acid, specific gravity 1.022; urea normal, uric acid in excess; blood count: reds, 4,804,000; whites, 12,400. The mild maniacal excitement continued for the first week after admission. The patient was very restless in the bed, moving her head from side to side and throwing her right arm overhead. She also often folded her arms rigidly across the chest and clenched the fingers. After the first week she slowly sank into a stupor, from which it was difficult to rouse her. The physical symptoms of central disturbance became rapidly more marked. There was entire loss of motion in the left arm, left leg, and later right leg, and extreme extension of both legs. The jaw became relaxed, interfering with respiration. The tongue fell back in the mouth. Breathing became jerky and irregular toward the end, and finally the relaxed jaw could not be replaced and death ensued. The autopsy was made by Dr. E. Wyllis Taylor, of Boston, who found a boggy, cyst-like mass extending back an inch behind the posterior border of the optic thalamus and forward to the junction of the caudate nucleus with the thalamus, the mass apparently involving the latter in its entire extent. Microscopical examination proved the tumor to be a vacuolar glioma. The mental symptoms in this case seem to have been quite unlike those of the usual cases of brain tumor recorded, in which are found depression, dulness, irritability, stupor, and even pronounced dementia. Several interesting questions arise, as, for instance: Which symptoms probably presented themselves first, the mental or physical? Why should there be so much mental disturbance in such a case? Was the mental trouble an accident and independent of the tumor? If not, how can it be satisfactorily explained? What diagnostic value do mental symptoms possess in cases of brain tumor?

DR. WHARTON SINKLER, of Philadelphia, thought that the appearance of mental symptoms in thalamus tumors was of much clinical interest. In his experience somnolence and mental symptoms were of frequent occurrence.

The Ectal Relations of the Right and Left Parietal and Paroccipital Fissures.—This was the title of a paper by DR. BURT G. WILDER, of Ithaca. The parietal and paroccipital fissures may be either completely separated by an isthmus or apparently continuous. When so continuous ectally, there may still be an ental and concealed vadum or shallow. Disregarding the vadum on the present occasion, the ectal relations of the two fissures may be designated as either continuity or separation. That continuity occurs more frequently on the left side has been noted by Ecker, Cunningham, and the writer. Hitherto, however, statistics have included unmated hemispheres as well as mates from the same individuals. The following statement is based upon the cerebrums of fifty-eight adults of both sexes and various nationalities and characters. The speaker had examined forty-eight; the other ten having been accurately recorded by Bischoff, Dana, Jensen, and Mills.

So far as these fifty-eight individuals are concerned, the most common combination, viz., left continuity and right separation, is decidedly the rule with the moral and educated, less frequent with the ignorant, the insane, and negroes, and does not occur at all in murderers. The only instance of the reverse combination (left separation and right continuity) was afforded by an insane Swiss woman. The only two known to be left-handed represented the more frequent combination of left continuity and right separation. These statistics suggest many special queries and problems, some of which were briefly indicated. But the speaker

wished this to be regarded as a preliminary communication, and asked the co-operation of other members in the effort to obtain satisfactory results of larger numbers, particularly of brains of well-born, moral, and educated persons. For this purpose a blank form was outlined.

Does Antisyphilitic Treatment Prevent the Occurrence of the Diseases of the Nervous System which are Considered Syphilitic in Origin?—DR. JOSEPH COLLINS, of New York, read this paper and pointed out that certain diseases of the nervous system occur sequentially to syphilis with such frequency that they are rightfully looked upon as syphilitic in their origin. These diseases are tabes, general paralysis, syphilitic spinal paralysis, and such exudative conditions as cerebral thrombosis. After briefly reporting the history and treatment in nearly one hundred cases observed in hospital, dispensary, and private practice, the writer concluded as follows:

1. Exudative and degenerative diseases due to syphilis are most liable to show themselves at the end of the third and beginning of the fourth decade of life.
2. Thorough and prolonged administration of anti-syphilitic remedies during the activity of the virus does not seem to materially advance this time limit.
3. That active and prolonged antisyphilitic treatment does seem to prevent the development of such diseases as locomotor ataxia and general paresis. This is true of degenerative diseases, though treatment may, however, have some effect in preventing the exudative diseases of the nervous system, such as syphilis of the spinal cord, disease of the blood-vessels, etc.
4. Cases of tabes and general paresis in which syphilis is confessed, and in which treatment has been most desultory and incomplete, are not more liable to the early development or to the severe manifestations of either of these two diseases than those in which the treatment has been all it should be.
5. That the administration of antisyphilitic measures in the most approved way does not fulfil the requirements of cure, and that syphilis is often an incurable disease.

DR. PUTNAM referred to a case that had received prolonged and thorough antisyphilitic treatment, yet symptoms of degenerative nervous disease appeared later in life.

DR. GRAY said that the facts in Dr. Collins' paper were not detailed as to the symptoms of syphilis nor as to the exact treatment. In many instances of suspected syphilis an absolutely positive diagnosis is at times almost impossible.

DR. SACHS agreed on the whole with the conclusions of the reader of the paper. In the vast majority of cases, however, the treatment of syphilis does not prevent the development of tabes or general paresis. A better way to have arranged statistics would have been to take all cases of syphilis and ascertain if they developed nervous disease later in life. The worst cases of syphilis of the nervous system occur in those who have never received any treatment. He spoke of such a person who had developed pronounced general paresis one year after the initial infection. In late cases it is often difficult to prove the relationship between syphilis and the nerve lesion. We should be careful about adopting Dr. Collins' views.

DR. P. C. KNAPP, of Boston, agreed with Dr. Sachs, and did not believe it wise to refuse antisyphilitic treatment when it seemed to be indicated. He asked Dr. Collins if his cases showed that the development of nervous disease bore any relation to the severity or character of the primary or secondary manifestations of syphilis. When the cutaneous symptoms were pronounced there was usually less nervous disturbance.

DR. OSLER said that his experience was opposed to

the views of Dr. Collins. The majority of severe cases of nervous disease occurring in syphilitics were in those who had either been badly treated or not treated at all. Early, thorough, systematic, and prolonged treatment will prevent the development of degenerative disease of the nervous system in later life.

DR. N. E. BRILL, of New York, asked how the reader could reconcile with his statistics the fact that anti-syphilitic treatment frequently cures incipient tabes and paretic dementia.

DR. DILLER had seen nervous disease develop in spite of early antisiphilitic treatment.

DR. PRESTON expressed the opinion that the irregularity with which endarteritis occurs is often overlooked. He was unable yet to establish the relationship between antisiphilitic treatment and endarteritis. Nervous disease has been of a milder type in those who have received careful early treatment, and more marked in those who have not.

DR. PATRICK said that the author's statistics did not prove that treatment was ineffectual, and that the nervous diseases might be due to other causes. When vigorous treatment is carried out for a brief period and then discontinued, late syphilitic disease of the nervous system is more likely to develop.

THE PRESIDENT maintained that it was hardly fair to draw conclusions from two diseases such as tabes and general paresis, as the reader acknowledged that they were not always due to syphilis. The degenerative affections may occur in cases that have been thoroughly treated.

DR. COLLINS, in closing the discussion, said that he wished it understood that he had no theories to advance, but had merely tabulated the results of these cases. Particular inquiry had been made in the cases detailed as to the kind of treatment, and in many instances satisfactory knowledge had been obtained. In cases which had been referred to by one of the speakers, in which the symptoms of tabes and general paresis disappeared under antisiphilitic treatment, he was not willing to concede that these were genuine cases of tabes or general paresis, but cases of pseudo-tabes and pseudo-paresis, in which the lesion was an exudative one and not a degenerative one, such as is characteristic of these two diseases, and it was his belief that in these cases antisiphilitic treatment was of benefit. He had purposely refrained from saying anything of gummata and had confined himself to the systematic syphilitic diseases of the nervous system.

Prognosis and Duration of Attacks of Mental Disease.—This was the title of a paper by DR. HENRY R. STEDMAN, of Boston.

DR. CHANNING called attention to the fact that a general misunderstanding occurs in the community as to the curability of insanity. It is much more curable than is supposed. General paresis should not be classified among the insanities. The character of the disease has changed in the last fifty years, and our views and classification have therefore changed.

DR. GRAY said that to speak of insanity as an entity was as if one were to speak of all disease as an entity, and then go back to the old Carlyle tables of mortality for the prognosis of coryza, pneumonia, tuberculosis, typhoid fever, and cholera, while to refer to the old statistics of Pliny Earle was like referring to the hospital results of thirty or forty years ago for guidance in the treatment of the present day. If we are to accept the statistics of results of the insane asylums, we are justified in analyzing their record, and then we are startled to find that no new type of mental disease, no original pathological observation, no new departure in treatment, and not one text-book has ever come from an American asylum, despite the millions of dollars and thousands of patients they have had at their command.

Second Day—Thursday, June 4th.

Progressive Muscular Atrophy of Sudden Onset.

—This was the title of a paper by DR. THEODORE DILLER, of Pittsburg. He related the details of a case which came under his observation three years ago, and stated that the sudden onset of palsy followed by atrophy and the absence of sensory phenomena led him to diagnose the case as one of poliomyelitis adultorum. The beginning of the patient's trouble was in an ophthalmoplegia. After an absence of two years the man again came under his care, when the atrophy and loss of power in the muscles had markedly increased. The biceps, triceps, scapular, and ulnar groups had become involved and the finer movements of the fingers were lost, as was also the power of supination. At this time the patient was unable to adjust or remove his clothing unaided. There was a marked decrease in the response both to galvanism and faradism in the paralyzed muscles. Dr. Diller considered the case could be fairly regarded as one of progressive muscular atrophy, as the progressive feature was for two years the most important feature of the case. Ophthalmoplegia as a symptom of progressive muscular atrophy must be rare, for but scant references are made to it in literature. Strychnine had a very marked effect in staying the progress of the disease.

Pitting about the Hair Cups a Trophic Change in the Skin in Certain Nervous Disorders of Central Origin.—DR. WILLIAM BROWNING, of Brooklyn, described a presumably hitherto unrecognized alteration in the skin. From some seven or eight years' observation of such cases he was able to give the limits of its occurrence. So far it has been seen only in progressive muscular atrophy of spinal origin or in cases complicated with atrophy evidently likewise due to chronic precornual disease. In other troubles attended by atrophy, as infantile palsy, neuritis, pseudo-hypertrophy, etc., it has not been found. It is hoped that it may prove a useful help in differential diagnosis, especially between the forms due to peripheral and central disease. The change consists of an areola-like faint depression, frequently oval, in the direction of the lines in the skin, though it may be irregular or circular in form, about the exit of each hair. Usually the depression is a trifle paler than the surrounding skin, resembling, but not really being, a minute scar. It is not observed in specially hairy regions like the scalp, but only over the seat of muscular atrophy, notably on the leg and thigh, though also on the upper extremities. All his patients had reached or passed middle life. A drawing to show the appearance in one case was exhibited.

A Case of Syringomyelia, Limited to One Posterior Horn in the Cervical Region, with Arthropathy of the Shoulder-Joint and Ascending Degeneration in the Pyramidal Tracts.—This was a paper by DR. F. X. DERCUM and DR. WILLIAM G. SPILLER, of Philadelphia. Three years after a strain of the back the patient began to suffer from pains in the legs, a band-like pain about the lower part of the chest, weakness in the lower limbs, and a spastic gait. Complete paraplegia with contractures, more marked on the right side, wasting of the lower limbs and paralysis of bladder and rectum developed later. Cutaneous sensibility was lost in the legs and upon the trunk as high as the nipple on the right side and a little above the umbilicus on the left. The sense of temperature was absolutely lost over the right arm, the right shoulder and the right side of the neck, and also upon the adjacent part of the right side of the trunk above the nipple line. There was some analgesia of the right arm. The right shoulder-joint began to swell and from rupture of the capsular ligament cellulitis with redness and local heat was produced, but with little or

no pain. In extension the humerus assumed the position of a subglenoid luxation. Death was due to exhaustion.

At the autopsy the capsule of the right shoulder-joint was found much thickened and roughened on the inner surface. The head of the humerus had disappeared, the bone having been eroded to some little distance below the surgical neck. A cystic tumor was found in the axilla containing a friable fatty material. The surface of the glenoid cavity was much eroded, roughened, and porous; it was abnormally large and extensive bony deposit had taken place along its edges. The coracoid process exhibited a thick and firm accretion around its entire edge.

Sections were made from the level of nearly every spinal root and from many spinal ganglia.

By the microscopic examination degeneration was found of the crossed pyramidal tract as high as the substantia reticularis of the second cervical segment and of the direct pyramidal as high as the motor decussation upon the right side, and for a short distance of the crossed pyramidal upon the left. This was believed to be ascending on account of the following facts:

1. Absence of any microscopic lesion above the medulla oblongata.

2. Degeneration of the crossed and direct pyramidal tracts on the same side of the cervical cord, intense in the lower cervical region near the lesion and diminishing gradually in intensity in the cervical segments, and finally becoming very indistinct in the upper cervical region.

3. Absence of all degeneration in the anterior pyramids.

4. Long duration of a chronic process.

While certain association fibres may be considered degenerated in these columns, the entire antero-lateral column contains such fibres, and the degeneration was notably in the area occupied by the crossed and the direct pyramidal tract. This ascending sclerosis was probably in greater part due to destruction of motor fibres deprived of their function.

Degeneration of the direct cerebellar tracts and of the tracts of Gowers was traced as far as the inferior peduncles of the cerebellum.

Intense pachymeningitis was noticed from the second lumbar segment to the exit of the third dorsal roots.

The arthropathy of the right shoulder was not due to any special changes in the cord or spinal ganglia.

The posterior roots were not affected even when the pachymeningitis was most intense; the anterior at one part of the dorsal cord were degenerated.

In the entire cervical region as high as the second cervical segment the cavity was limited to the right posterior horn.

The gliosis extended from the extreme end of the conus terminalis to the second cervical segment. The microscopic examination explained satisfactorily the symptoms observed in life.

Rapidly Fatal Cerebritis Resembling Cerebro-Spinal Meningitis.—This was a joint paper by DR. JAMES HENDRIE LLOYD and DR. JOSEPH SAILER, of Philadelphia. The writers called attention to the fact that fulminating cases of the infectious diseases, such as small-pox, scarlatina, measles, typhoid fever, and spotted fever, occur in which the diagnosis is exceedingly obscure and the disease is usually quickly fatal. These cases as a rule have their most marked symptoms in the nervous system. There is delirium passing into coma, with depressed cardiac and respiratory centres, with high fever, and in the cases of the exanthema often a purpuric or hemorrhagic eruption not always characteristic. These cases demand especially two things, first, the determination of the exact effects

upon the nervous system, and second, the determination of the microbe or toxic agent at work in any given case. The writers could attempt only the former study, as the paper was not intended to deal with the bacteriology of the subject.

The patient was a man, aged twenty-four years, who was taken suddenly with a chill followed by fever and intense cephalalgia and radialgia. The patient passed rapidly into a condition of delirium merging into coma. Third-nerve paralysis supervened, and on the third day a copious purpuric eruption appeared. This eruption presented ecchymosis, and on the hands lesions like erythema nodosum. Blood and pus were found in the urine and vomiting of blood occurred before death. The patient died on the sixth day. The autopsy revealed disseminated local lesions in the cerebrum, mid-brain, pons, and post-oblongata; some migrated leucocytes in the perivascular spaces, little involvement of the membrane, and a diffused nephritis. From extensive microscopic research the writers were able to report a disseminated local cerebritis. The infection had invaded the brain by way of the connective-tissue structures, blood-vessels, etc., and the nerve tissues proper were invaded secondarily. From the clinical standpoint the case probably comes under the head of "spotted fever."

DR. OSLER said he would have liked to hear in regard to the condition of the kidneys in the case reported. The diagnosis of cerebritis and encephalitis can be readily made between cases of infectious fever and the former. Unless the basal meninges are involved we cannot make a positive diagnosis of meningitis, as all those symptoms, such as retraction of the head and clonic contractions of the muscles, may be present in pneumonia and yet nothing be found at the autopsy.

DR. PUTNAM agreed with the previous speaker that so-called meningeal symptoms may occur without meningitis.

DR. CHARLES K. MILLS and DR. WILLIAM G. SPILNER, of Philadelphia, reported the following case: The patient had never had earache, but had suffered during the summer of 1895 from severe headache. On December 20, 1895, he became unconscious and had three general convulsions which resembled those of epilepsy. It was noticed that he was partially paralyzed on the right side and that he could not talk properly. His condition later improved very much. On January 29, 1896, he had another attack of partial unconsciousness without convulsions, but with aphasia and decided paralysis. On admission to the hospital he was in a condition of stupor, he did not speak when addressed, and had almost total right-sided paralysis, incontinence of urine and feces, and entire loss of pain and touch sense over the paralyzed side. He was found to have right homonymous hemianopsia, and double papillitis, most marked in the left eye. Death occurred February 26, 1896. There was no evidence at any time of middle-ear disease. At the autopsy an abscess was found in the left hemisphere, just above the level of the callosum. Both tympanic membranes were normal. Microscopic examination of the pus from the cerebral abscess revealed only the ordinary staphylococcus pyogenes aureus. The occurrence of epileptiform convulsions at the time of the first attack of unconsciousness, probably due to irritation of the motor fibres within the internal capsule, is worthy of note as an instance of the difficulty in diagnosing cortical lesions. It is not known in what portion of the body these convulsions began. The diagnosis was made of some morbid process located at the posterior part of the internal capsule involving the optic radiations and causing pressure. The abscess occupied the posterior part of the external capsule, a portion of the lenticular nucleus, and extended

downward into the subthalamie region, but to all appearances had not cut the fibres of the optic radiations nor those of the internal capsule. The loss of function in these tracts was probably due to pressure. The white matter of the first temporal gyrus was almost entirely destroyed, and fibres from the upper anterior part of the second temporal were also cut. As the cavity was very near the periphery of the first temporal convolution it would not have been difficult for the surgeon to have emptied it. Hearing was probably not seriously affected, although word deafness appeared to be present. In view of the frequency of cerebral abscess after suppurative processes in the lungs, it may be added that merely spots of catarrhal pneumonia were found in both lungs at the autopsy. No degeneration was noticed anywhere in the motor tract. At all parts a good half-inch of sound tissue existed at the posterior part of the internal capsule in the area corresponding to the optic radiations and the tract of Türck. It has been claimed by Déjérine that fibres arise in the temporal lobe (especially in the second and third convolutions), pass inward below the putamen, join the posterior part of the internal capsule in the subthalamie region, and then form approximately the external fifth of the cerebral peduncle. No fibres from the occipital lobe are found in this lateral bundle of the crus. Déjérine has found this tract of Türck degenerated in six cases of lesions involving the middle and inferior part of the temporal lobe.

In this case the fibres from the first temporal gyrus were almost entirely destroyed as well as those from the upper anterior part of the second temporal convolution, and as no degeneration has been found within the lateral bundle of the peduncle by the method of Marchi, sixty-eight days after the first attack and twenty-eight days after the second, certainly a period sufficiently long for this method, we consider that the case demonstrates the fact that no fibres from the first temporal and the upper anterior part of the second temporal gyrus, including a portion of the upper middle of this gyrus, enter the fasciculus of Türck. This, of course, does not render impossible or improbable the origin of such fibres in the lower anterior and the whole of the posterior part of the second temporal, and in the whole of the third temporal gyrus. The fibres which enter the first temporal gyrus are probably connected with the sense of hearing, and being sensory probably do not degenerate downward, which accounts for the absence of secondary degeneration in the peduncle.

The Surgical Treatment of Focal Epilepsy; a Critical Analysis of the Result in Nineteen Cases.

—DRS. B. SACHS and A. G. GERSTER, of New York, presented a paper with this title. For the last six years the authors have attempted to study in a thoroughly unbiased fashion the results of the various surgical procedures for the cure or relief of partial epilepsies. They include not only cases due to traumatic injury, but those associated with infantile cerebral palsies or some other acute cerebral condition. Their list of cases does not, however, include those in which the epilepsy is due to tumor. Before detailing their own cases the authors lay special stress upon the unsatisfactory results to be gained by a mere statistical inquiry of the cases reported in literature. The majority of these are reported either too early, or, if reported, the cases are not properly analyzed. It is their opinion that the results after operative procedures for the cure of epilepsy should not be considered unless at least a period of one year has elapsed since the time of the operation. But they also state that it is not well to exclude all cases in which the attacks return soon after the operation, for in some of these decided improvement sets in later on. A number of authors have condemned every surgical procedure

without in the least attempting to account for the failure to cure or to improve the patient. Thus the mere fact of an addiction to alcohol is of itself sufficient to explain the failure to cure epilepsy by operative procedure. The epilepsy which is developed after a traumatic injury or in association with infantile cerebral palsies is evidently due to secondary degeneration of the association fibres in the hemispheres, for this degeneration originates from the focus of diseased tissue, and the epilepsy is generally developed in the course of a year or two. In this same period of time the epilepsy often appears after the initial injury. Horsley's proposition to excise the diseased tissue and thus prevent the epilepsy is considered to be based upon sound physiological principles, but in practice the results have not been so satisfactory as was expected, and the authors attribute this chiefly to the fact that after an epilepsy has lasted for a number of years and after secondary degeneration has been fully established, the excision of the original focus of disease cannot be expected to do good. It is important therefore, if possible, to prevent the formation of secondary degeneration in the hemispheres by excision of the diseased tissues, or to prevent epilepsy by early surgical procedures in the case of depression of the skull and other cranial injuries. The authors' nineteen cases have been minutely tabulated with reference to the origin of the trouble, the interval elapsing between the traumatic injury or beginning of the epilepsy and the operation. The analysis of the nineteen cases shows that three were positively cured, two greatly improved, three somewhat improved, while in eleven cases there was absolutely no improvement. A study of all the cases shows that those in which there has been improvement the operation was done within a period of two years after the traumatic injury or the beginning of the disease. The same is true of those cases that were greatly improved but not cured, the failure to cure in these cases being ascribed to other causes, such as alcoholism or want of proper care after operation. The authors' views and experiences are summed up in the following conclusions:

1. That surgical interference is advisable in those cases of partial epilepsy in which not more than one or at the utmost two years have elapsed since the traumatic injury or beginning of the disease which has given rise to the convulsive seizures.

2. In case of depression or other injury of the skull surgical interference is warranted even though a number of years have elapsed, but the prospect of recovery is brighter the shorter the period of time since the injury.

3. Simple trephining may prove sufficient for a number of cases, and particularly in those cases in which there is an injury to the skull, or in which a cystic condition is the main cause of the epilepsy.

4. Excision of cortical tissue is advisable if epilepsy has lasted but a short time, and if the symptoms point to a strictly circumscribed focus of disease.

5. Since such cortical lesions are often of a microscopical character, excision should be practised even if the tissue appears to be perfectly normal at the time of operation, but the greatest care should be exercised in order to make sure that the proper area is removed.

6. Surgical interference for the cure of epilepsy associated with infantile cerebral palsies may be attempted, particularly if too long an interval has not elapsed since the beginning of the palsy.

7. In cases of epilepsy of long standing in which there is in all probability a widespread degeneration of the associated fibres, every surgical procedure is absolutely useless.

A Contribution to the Pathology of Epilepsy and a Résumé of the Utility of Operations in Epilepsy.
—By DRS. JOSEPH COLLINS and A. WIENER, of New

York. This was a report of two cases in which a portion of the cortex was excised. The first case was that of a young man, twenty years of age, with the usual symptoms of focal epilepsy, the patient having had but three attacks. The cortical area for the right hand was cut out. Microscopical examination of the tissue showed chronic meningo-encephalitis, obliterative changes in the blood-vessels, changes in the ganglion cells of a degenerative character, and the formation of neuroglia tissue in the softened area. The patient was operated upon a year ago and has since been free from epileptic attacks. The second case was that of a married woman, thirty years of age, who had epilepsy for six years of a focal character at first, which later became general. A similar operation was performed and the cortex showed unmistakable pathological changes.

DR. W. W. KEENE, of Philadelphia, and H. M. THOMAS, of Baltimore, reported a case of a large tumor removed from the brain with wide opening of the lateral ventricle. The patient, a young man of nineteen, with an excellent family and personal history and no history of accident, in December, 1895, had an attack of intense headache and vomiting, but without optic neuritis. The latter symptom followed in the middle of January, with later blindness in the right eye, slight vision remaining in the left; slight protrusion of left eyeball, pupils equal and normal; smell, hearing, and taste unaffected; paresis of the lower right face; sensation and the muscles of mastication unaffected, no muscular weakness in either the arms or legs, but a good deal of muscular restlessness of the right hand, persisting even during sleep; reflexes present; mental condition poor. He was dull and apathetic and sometimes slightly wandering mentally. After the early headache and vomiting, neither of these was a marked feature. There was slight aphasia. Drs. Osler and Starr saw the patient with Dr. Thomas, and the conclusion was reached that it was a tumor in the left frontal lobe, most likely at the base of the second frontal convolution and probably subcortical. On May 10th, Dr. Keene operated. The tumor presented through a rupture of the cortex at the base of the second frontal convolution, as had been diagnosed. The tumor was easily scooped out by the fingers. The lateral ventricle was then seen to be widely open. After the operation there was no increase of the paralysis. In two weeks the patient had entirely recovered. The tumor was 7.5 centimetres long, 5.5 centimetres broad, and four centimetres deep, and weighed two and a half ounces. It was a hard non-infiltrating sarcoma.

All of the foregoing papers were discussed collectively.

DR. A. G. GERSTER, of New York, confined his remarks principally to craniotomy in reference to cases of epilepsy. He spoke of the dangers in the use of the trephine and chisel and recommended the bone-flap operation as introduced by Krause and performed by aid of the chisel and rongeur. He considered all of these methods unsatisfactory and too slow. Incidentally he exhibited Krause's electrical saw.

The greatest danger in cranial operations is due to hemorrhage on account of the prolonged time of the operation. Therefore any apparatus is desirable that will enable the surgeon to work with rapidity and safety. He presented an American apparatus based on the principles of the dental drill, and said he had used the instrument with satisfaction in four cases.

DR. M. A. STARR had seen twenty-four cases operated upon, but none was cured. He has never recommended, and will not recommend, operation in idiopathic epilepsy. He has always had the advantage of a skilful operator. These operations should only be done by surgeons who have special experience in this

line of surgery and not by the general surgeon. The excision of cysts is very unsatisfactory, as death on the table has often followed. He had seen cases operated on very early in infantile epilepsy due to meningeal hemorrhage without favorable result. When brain tissue, either scar tissue or normal tissue, has been excised, the attacks have also recurred. Of eleven patients with brain abscess operated upon, three recovered. All of these cases were seen at the various hospitals and were usually subsequent to ear disease. He could not agree with Macewen's view as to the simplicity of diagnosis of cerebral abscess. He thought the day of trephining was over. The last operation witnessed was done in fourteen and a half minutes by chisels and gouges.

DR. W. W. KEENE spoke at length on the report of the case presented conjointly by him and Dr. Thomas, and considered the prognosis favorable. The removal of large tumors seems to be less dangerous to life than that of small ones, as in the search for the latter we are likely to damage the brain extensively. It is only within the last ten years that cranial surgery really began. His experience had been moderately large. He agreed with Dr. Starr, as he (Dr. Keene) had not seen a single case of epilepsy cured by operation. He would be unwilling to accept even two years, but thought three years preferable as the limit for disappearance of attacks after operation. He had, however, seen considerable amelioration, and therefore thought it worth while to operate in certain cases. He would not operate in cases of general idiopathic epilepsy. The sooner the operation is done after the injury or the beginning of epilepsy the more favorable the prognosis. After epilepsy had existed five or six years, he would hesitate in operating. He concluded that we must have twenty years of experience in cerebral surgery before this matter can be satisfactorily settled by the profession.

DR. J. R. LLOYD presented a patient with right hemiplegia and contracture, unilateral sweating and flushing of the face and dilatation of the pupil, and looked upon the latter symptoms as due to an irritative lesion of the thalamus.

Third Day—Friday, June 5th.

Edema of the Eyelids in Graves' Disease; Thyroidectomy.—DR. J. ARTHUR BOOTH, of New York, read a paper on this subject (see p. 45).

DR. STARR expressed the opinion that operations in these cases were not always safe, the percentage of death being twelve out of one hundred and eighty-seven cases. Sudden deaths have occurred soon after the operation. They were not due to surgical shock, but to the absorption of thyroid juice during the operation, thus overwhelming the system by its toxic properties. The operation of thyroidectomy should not be done indiscriminately.

A Form of Mental Disease Clinically Resembling Certain Stages of Paretic Dementia.—BY DR. E. C. SPITZKA, of New York. The reader had found in a long experience sixteen cases of an affection most important to differentiate, as the termination was in recovery. So close was their resemblance *pro tem.* to paretic dementia, that in every instance that or the equivocal diagnosis of "softening" had been made. The writer himself had at first regarded them as pertaining to Voisin's atheromatous insanity or to his own group of primary mental deterioration. The speech disturbance was peculiar, being more like that of febrile delirium than that of a toxic or organic anarthria. By concentrating his attention, the patient could correct his errors, and it was the longest words and those of most difficult enunciation which he pronounced as readily as most persons of average health

and education. Repeated trials rapidly fatigued him, and while no real parietic speech could thus be provoked, he was as apt to say "there is rumthing sodden in the den of statemark" as to quote the passage correctly. When an expression failed him, he displayed considerable skill in circumscribing his meaning by the use of metaphorical or parallel expressions. A similar feature was found in that similar condition—bromism. The earliest case of which he had a record occurred in October, 1879, and was recorded by him as one of chronic confusional insanity, with a reservation as to probable atheromatous sequelæ. The patient exhibited a typical confusional delirium. His age (sixty-four), the arcus senilis, the tortuous temporal arteries, and the characteristic pulse were suggestive. He was promptly committed to an asylum on his advice. In February, 1881, he appeared in his office, and had made a recovery. This patient was alive and in good health three years ago. Among the etiological factors, syphilis and alcohol could be excluded. Grippe, malaria, railway injuries, dysentery, and chronic bronchitis played a predisposing rôle. Recovery occurred in from four to fourteen months. The ages of his patients ranged from forty-eight to seventy-one years. He had found the last eleven cases recorded among males exclusively not quite two per cent. of a group of cases including five hundred and eighty-five parietic dementes, forty-one of atheromatous mental trouble, and twenty-eight of primary mental deterioration.

Nerve Disturbance from Indigestion.—By DR. HENRY S. UXON, of Cleveland. The paper dealt with the nervous disorders arising from intestinal indigestion. Three cases were given, one of the nervous phenomena arising in typhoid fever, in brief as follows: A young man of twenty-four was seen at the end of the first week of typhoid. Besides the typical temperature curves, enlarged spleen, nose-bleed, backache, and other symptoms, he was even thus early somewhat delirious during the day and quite sleepless at night. Thymol and hydrochloric acid failed to relieve, one-sixth of a grain of morphine with twenty grains of Dover's powder did not produce sleep, and within a week there were coma, vigil, and subsultus tendinum. The bowels had been throughout very constipated. During the third week of the disease sleep followed very promptly the clearing of the bowels by calomel, an eighth-grain every hour during the day and every two hours during the night. The second case was of a merchant, sixty years old. He was seen two weeks after recovery from a severe attack of dysentery. The diarrhœa had been checked by the free use of opium. He was in a state of what may be termed restless melancholia. He was very nervous, cried easily, slept almost none. There were rumbling and moderate pain in the bowels, with occasional somewhat offensive movements. The patient was given strontium salicylate and calomel, and was restricted to a milk diet. He began to sleep fairly well at night, was contented to remain in the hospital, and his extreme pallor and fairly marked anæmia with his other symptoms improved slowly but steadily. The third patient showed a similar train of symptoms after a mental shock. She gradually developed a condition of depression, nervous irritability, and sleeplessness after hearing suddenly that her husband had accidentally shot himself, and in spite of the fact that he made a good recovery. She was first seen five months after this event. In addition to the symptoms already given, she had rumbling and some tenderness of the bowels, but there was neither diarrhœa nor marked constipation. Her condition improved promptly on a milk diet and one of the salicylates. Conclusions were not warranted from so few cases, but the author believed from a somewhat extended experience in these cases

that the type of nerve disturbance found in typhoid, and in connection with and after dysentery and diarrhœa, is found in intestinal indigestion without the intervention of these disorders, may easily be confounded with mild melancholia and neurasthenia: it presents many points of similarity to nicotine poisoning, it must be carefully differentiated from nerve disorders arising by reflex, it is amenable to treatment, which should not consist exclusively in the administration of an antiseptic.

Report of the Committee on Neuronymy.—DR. B. G. WILDER presented the report.

Among the recommendations of the committee were:

1. That the adjectives dorsal and ventral be employed in place of posterior and anterior as commonly used in human anatomy, and in place of upper and lower as sometimes used in comparative anatomy.

2. That the cornua of the spinal cord and the spinal nerve roots be designated as dorsal and ventral rather than as posterior and anterior.

3. That the costiferous vertebræ be called thoracic rather than dorsal.

4. That the hippocampus minor be called calcar; the hippocampus major, hippocampus; the pons Varolii, pons; the insula Reilii, insula; pia mater and dura mater respectively pia and dura.

5. That, other things being equal, mononyms (single-word terms) be preferred to polyonyms (terms consisting of two or more words).

Newspaper Rabies.—This was the title of a paper by DR. IRVING C. ROSSE, of Washington, D. C. He referred to the frequency with which hydrophobia was mentioned by the public press at this season. Late papers on the subject show that there is still a chaotic knowledge of this badly elucidated affection, concerning which surgeons and neurologists are by no means agreed. From examining a great mass of literature relative to rabies, while working on the index catalogue of the surgeon-general's office, Dr. Rosse stated that he came across hundreds of references to hydrophobia of a spurious character, and that these references date from the Homeric era to that of Cellius Aurelianus. Much other literature was also cited, showing that in by-gone times there were skeptics as to the existence of such a pathological entity as hydrophobia. As an extensive traveller in parts of the world where this disease is supposed to occur geographically, he had never seen a case, nor had he any authentic knowledge of one from personal observation. The secretary of the Japanese legation in Washington says he has never known of a case in Japan, and that in Corea, having more dogs than any other country in the world, hydrophobia is unheard of. A few Italian and French physicians and the newspapers appear to be the chief contributors at the present time. The reader thought that, in view of the uncertain state of knowledge of the subject, the newspapers are hardly to blame for reckless accounts of hydrophobia, since they only hold the mirror up to nature, and, reflecting public sentiment, give us, so to speak, a radiograph of what is passing in the minds of medical men.

The Collateral Theory of Epilepsy.—DR. F. W. LANGDON, of Cincinnati, presented a paper entitled "Epilepsy and Other Convulsive Diseases—A Study in Neuro-Dynamics." His conclusions were:

1. That epilepsy, the choreas, and probably most of the convulsive disorders are the dynamical expression of an inhibitory insufficiency, not indications of overproduction of nerve energy nor "explosions" due to a "molecular instability" *per se*.

2. That the cause of this inhibitory insufficiency is to be sought for in the end brushes of the collateral processes of various cortical neurons, the situation varying with the "type" of the disease, whether sensory, psychic, or motor.

3. That the defect consists most probably in a structural incompleteness (small capacity, defective insulation, imperfect contact) or a numerical deficiency, or both, in the collateral processes of the neurons referred to.

4. Defective collaterals may favor occurrences of convulsions in two ways: (a) by impairing connection with other neurons (inhibitory, storage, etc.); (b) by increased resistance to "overflow currents" causing temporary overcharging of motor axis cylinders. This conception of the anatomico-dynamic basis of convulsive phenomena he would call "collateral theory."

On this basis cases of epilepsy are classed under three groups, each of which presents important differences as regards prognosis and treatment.

1. Primary, or developmental type, comprising the "idiopathic" cases under twenty years of age. In these, the younger the subject and the better the heredity and environment, the better the prognosis under intelligent treatment, ultimate result depending on the possibility of promoting further and equable development of collateral communications with inhibitory mechanisms.

2. The "accidental" forms: These are due to trauma, syphilis, lead, toxins, etc. The prognosis varies with the longer or shorter duration and the possibility of removal of the cause; being always favorable so long as permanent structural changes in collaterals and inhibitory mechanisms have not occurred.

3. The "degenerative" type: The rare cases of adult life and old age (not accidental) belong in this category. Here palliation only is to be expected, as in the case of degenerative changes elsewhere. In all forms the rational indications for treatment are: To lessen the incoming sensory excitation, by diet, occupation, medicines; and so lessen the intensity of motor responses which are not provided with suitable overflow and inhibitory mechanisms.

Election of Members.—The following-named gentlemen were elected to active membership: Dr. F. K. Hallock, of Cromwell, Conn.; Dr. John Punton, of Kansas City; Dr. Alfred Wiener, of New York; Dr. Henry J. Berkley, of Baltimore; Dr. F. W. Langdon, of Cincinnati.

Election of Officers.—The officers elected for the ensuing year were: *President*, Dr. M. A. Starr, of New York; *Vice-Presidents*, Dr. H. R. Stedman, of Boston, and Dr. H. S. Upson, of Cleveland; *Secretary and Treasurer*, Dr. G. M. Hammond, of New York; *Councillors*, Dr. F. X. Dercum, of Philadelphia, and Dr. Joseph Collins, of New York.

Epispadias.—The following operation for the relief of epispadias seems theoretically correct and has yielded satisfactory results in two cases. The steps are as follows: 1. A perineal fistula, made by cutting from the outside, upon the finger introduced into the bladder above to distend the perineum or by the use of Watson's perineal drainage tube. The subsequent steps may be proceeded with at once or ten days after, when time and rest have allowed drying and healing of excoriations. 2. Dissecting-up of the urethra, which lies open upon the upper surface of the perineum. 3. Separation by blunt dissection of the loosely connected cavernous bodies. 4. The urethra, laid in the gutter then formed, is secured by two sutures through lower floor of urethra and skin of under surface of penis. 5. The free edges of the urethra are united with continuous catgut ligature over a silver catheter extending to bladder. 6. The cavernous bodies are then united with continuous catgut and the skin, which is usually abundant, with interrupted silkworm gut.—CANTWELL (*Annals of Surgery*, December, 1895).

Surgical Suggestions.

Surgery of the Lung.—Dr. Paul Reclus, at the ninth French Surgical Congress (*La Médecine Moderne*, October 23, 1895) discourses on this subject and concludes: 1. That surgical interference in cases of tuberculosis must be proscribed. 2. In primary cancer no conditions can arise in which pneumonectomy would be feasible. 3. Where there are cavities incision is sometimes a justifiable palliative measure. 4. Resection of a portion of the lung is a last recourse for hemorrhage. It has been successful in three reported cases. 5. Incision is beneficial in hydatid cysts, gangrene, and abscess. The intervention in these cases is radical, but sometimes saves the life of the patient.

Treatment of Fibroid Tumors by Ergot.—Prof. W. H. Byford begins his chapter on this subject as follows: "1. When properly administered ergot frequently greatly ameliorates some of the troublesome and even dangerous symptoms of fibrous tumors of the uterus, e.g., hemorrhage and copious leucorrhœa. 2. It often arrests their growth and checks hemorrhage. 3. In many instances it causes the absorption of the tumor, occasionally without giving the patient any inconvenience; at other times removal of the tumor by absorption is attended by painful contractions and tenderness of the uterus. 4. By inducing uterine contraction it causes the expulsion of the polypoid variety. 5. In the same way it causes the disruption and discharge of the submucous tumor."

Sterilization of Catgut.—The thread should be rolled on a piece of glass and left in ether a day, then put into nitrate of silver in a dark-colored vessel full of the solution. Prepared in this way the catgut preserves its flexibility. It should be kept in alcohol or juniper oil.—*Pract.*, No. 51, 1895.

The Relation of Trauma to Malignant Tumors.—Dr. Zugler reviews this subject in the *Münchener med. Wochenschrift*, Nos. 27 and 28, 1895. He bases his paper on the statistics of the last five years in the surgical clinic in Munich. In all there were 328 cases of carcinoma, 117 in men and 211 in women; and 171 sarcomas in 81 men and 90 women. After deducting tumors of the mamma and genital organs there were 108 tumors in men and 102 in women. In the carcinomas there was a history of single traumas 55 times. There had been chronic irritation 92 times. In the sarcomas a single trauma was noted 35 times, and 32 times chronic irritations (including warts) were at fault. Some cases of single trauma seem to stand in doubtful relation to the formation of the growth, but as a rule the new formation has been occasioned by injury. The writer bases his opinion on the continuation of the pains and swellings after the trauma, which go insensibly into the formation of the tumor. Dr. Ziegler adopts Virchow's irritation theory of the high percentage, twenty-five per cent. for single trauma, and eighteen per cent. for continuous irritation. The influence of trauma should be considered, no matter what theory of tumor formation one accepts. The subject becomes important in connection with medico-legal procedures and accident insurance.

Chronic Middle-Ear Suppuration.—Dr. Wilson (*New York Medical Journal*, March 28, 1896) says the continuance of the process is due to various causes, the most important of which are: 1. The development of granulation on the mucous membrane of the tympanic cavity. 2. The retention of masses of exudation. 3. Lesions of the bony walls of the cavities. 4. Disease of the naso-pharynx.

Hysterectomy.—Dr. Ashton (*Medical Bulletin*, January, 1896) says the conditions indicating hysterectomy for puerperal septicæmia are: 1. Suppurative inflammation of the uterus. 2. Tubal and ovarian abscesses. 3. Abscesses of the broad ligament. 4. Rupture of the uterus.

Vaginal Hysterectomy.—Dr. Davis reports twenty-one consecutively performed cases of this operation. It may be employed: 1. In all cases where we determine to perform double oöphorectomy. 2. In double pyosalpinx or salpingitis. 3. In single oöphoro-salpingitis where we have unyielding, chronic urethritis. 4. In severe displacements near the menopause and all others not yielding to treatment. 5. Tumors of the uterus, interstitial or subperitoneal, not exceeding a child's head in size. 6. In all cases of malignant diseases of the fundus and cervix, when not involving the vaginal or pelvic walls. 7. In small cysts and other growths of one or both ovaries and tubes near the menopause. 8. In all cases of chronic peri-uterine phlegmasia, with or without suppuration, not yielding to other treatment.—*Journal of the American Medical Association*, February, 1896.

Brain Surgery.—Dr. Edward D. Fisher, of New York, said that the indications for operation are (1) traumatism, (2) localized epileptic seizures, (3) athetosis with or without epilepsy, (4) tumors, (5) abscess, (6) cerebral hemorrhage, and (7) microcephalus.—*Report of Medical Society of the State of New York*, January, 1896.

Tumors of the Thyroid Gland.—Dr. Cook (*British Medical Journal*, June 8, 1895) considers the following conditions as indications for removal: 1. If the tumor be steadily increasing in size. 2. If there be troublesome pressure upon the trachea, œsophagus, or nerves. 3. If the tumor be so placed as to render impossible a possibly necessary tracheotomy. 4. If the patient strongly urge its removal because of its unsightly appearance or its interference with the movements of the head.

The Antiquity of Anæsthetics.—Dr. Hupp writes in the *New York Medical Journal*, March 28, 1896: "Morton discovered anæsthesia, and a priceless blessing it has been to mankind, for it has already saved thousands of lives and is 'destined for all time to come to compound the sum of human happiness.' But anæsthesia did not begin with the lamented Morton. We are told somewhere in the Holy Writ that 'a deep sleep was caused to fall upon Adam and he slept,' and it was during this sleep in the Garden of Eden we are further told of the first surgical operation: an exsection of a rib, for 'bone of his bones' was taken from his side and the flesh closed up instead thereof, and in this way his helpmeet Eve was fashioned and in 'soft attractive grace' brought unto him."

Gonorrhœa.—Dr. Janel (*Ann. des Mal. des Org. Gén.-Urin.*) uses potassium permanganate in the acute stage to prevent chronic inflammation of the urethra. The parts are thoroughly cleansed to remove all the gonococci possible and to prevent secondary infection. A dilute solution of sublimate should also be used. Superficial and fresh lesions of the bladder should be washed and treated with a solution of nitrate of silver administered a drop at a time. After infective germs are destroyed it is proper to begin instrumental examination. Superficial and fresh lesions may be treated as above, deeper and old lesions with dilatation, and localized inflammations with the urethral endoscope. Both parts of the urethra must be treated, even though the penile portion alone shows lesions.

Dr. Shoemaker thinks rest an important element and advises keeping the patient in bed a week, after hav-

ing first given a saline cathartic. All condiments and stimulants should be forbidden. The penis and scrotum should be supported. A blennorrhetic should be administered in small doses and the amount increased to the limit of toleration. Copaiba and cubebs may be given alone or in combination. An alkali may be given in addition, and in case of great pain a small quantity of morphine sulphate. Oil of sandalwood two or three times daily in five-minim doses is also an effective remedy.

Closing Arterial Wounds by Suture.—Dr. Heidenhain, in the *Centralbl. für Chir.*, No. 49, 1895, cites two previously recorded cases, involving in one instance the common femoral, in the other the common iliac. He also reports a case of his own, in which during the removal of some cancerous glands from under the armpit, and after necessary resection of a portion of the axillary vein, a wound about an inch and a half in length was accidentally made in the main artery. The bleeding was arrested by digital compression and the edges of the arterial wound were brought together by a continuous suture of catgut. The bleeding was thus completely arrested. The lumen of the vessel was not apparently diminished. The sutures held firmly in spite of strong arterial pulsation. The patient made a good recovery, and when last seen, seven months after the operation, was quite free from relapse. The axillary artery could be felt pulsating along the whole extent of the armpit.

Orificial Surgery.—The logical conclusion to be formed from the teachings of orificial specialists is that the rectum is the focus of existence, contains the essence of life, and performs the functions ordinarily ascribed to the heart and brain.—*New York Polyclinic*.

Cleft Palate.—Dr. Broca considers it unnecessary to wait until a child is two or three years old before operating. He does not hesitate to operate on a child of from three to six months old, provided it can have proper attention.

Hepatic Abscess.—Dr. M. Fontan (*International Medical Journal*), who has treated forty cases of abscess of the liver following dysentery contracted in tropical countries, adopts the following rules for operating: 1, a free incision eight or ten centimetres long; 2, the final resection of one or more costal cartilages to expose the abscess freely; 3, the separate suturing of the peritoneum and of the pleura; 4, the complete curettage of the cavity of the abscess.

Intestinal Anastomosis—Mannell's Method.—1. The longitudinal slit which is made in the segment of the bowel having the greatest calibre (proximal or distal), and through which the invagination occurs, should be located at least two inches from the cut end of the bowel. 2. The mesentery of both segments must be included in the first temporary suture which is passed at this intestinal border: this prevents sloughing of the bowel at this point. 3. The sutures should be placed at least a quarter of an inch from the cut intestinal edge; they should be interrupted, about twenty in number, and should not be drawn too tightly when they are tied. 4. The best suture material for the work is carefully tested and prepared horsehair. 5. The needle best adapted to this work is a round, straight one (milliner's, Nos. 6 to 9). 6. The invagination, after the sutures have been placed, must be carefully reduced, rather by manipulation than by traction: otherwise the sutures may cut out. 7. In closing the longitudinal slit, too much of the intestinal edges should not be turned in, or a contraction may result at this point.—WIGGIN, *New York Medical Journal*, December 14, 1895.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MEDICAL COUNCIL—COMING ELECTIONS—ARMY MEDICAL SERVICE AND ITS GRIEVANCES—SPLENIC ANÆMIA—LORD KELVIN'S JUBILEE—HOSPITAL SUNDAY—SIR T. G. LOGAN.

LONDON, June 19, 1896.

THE General Medical Council having finished its session, we are now speculating on the results. Some important questions which were postponed may perhaps be determined differently from what would have been the case had the vote been taken at the late meeting. Some new members appeared at the last session, as I have already reported, but there will be more new blood at the next, as we shall have fresh elections for direct representatives. In Scotland, Dr. Campbell Black, an energetic reformer, will come forward as a candidate. The Rev. S. Haughton, M.D., has resigned the seat for Trinity College, Dublin. In England two of the three representatives, Sir W. Foster and Mr. Wheelhouse, have signified their intention not to seek re-election. In the letter announcing this they insist that they have never failed to advocate the views of their constituents, so far as compatible with the acts, and advise a "very deliberate and careful choice" of their successors. This would be a contrast to the manner in which they themselves obtained their seats, through the disgraceful action of the British Medical Association clique in direct opposition to a resolution of the association. But this old story was duly told by your correspondent at the time. It will be interesting to see if the early announcement is intended to prepare the way for a similar electioneering proceeding or only for a "very deliberate and careful choice."

On Tuesday Dr. Farquharson once more called the attention of the House of Commons to the army medical service with reference to the difficulty of obtaining candidates in consequence of the still unredressed grievances of the medical officers. He asked whether the new warrant spoken of would be promulgated before the next examination, but the official reply was most unsatisfactory and professed ignorance as to whether a warrant would be issued. The case of Surgeon-Captain Fowler comes before the house to-day, and unless "my military advisers" retreat there may be an unpleasant quarter of an hour for them. Dr. Anderson's case is being pushed by the Civil Rights Defence Committee, and there are other object lessons for the public and Parliament which may lead to retribution. As to army surgeons, the authorities expected to get a supply from the Irish schools, but the most influential teachers there have warned the students that if they become candidates before a satisfactory warrant is issued they will injure those already in the service and have to submit to the grievances under which their brethren labor.

A considerable number of army men were at their annual dinner on Monday, when the new director-general of the department was in the chair, supported by his predecessor. Of course this was no occasion for the ventilation of grievances.

Splenic anæmia has been before the Medico-Chirurgical Society. Dr. S. West related a case very fully, and several others were mentioned by different speakers, so that the disease would seem to be less rare than the number of recorded cases—about twenty—might lead us to suppose. The usual course of the disease is gradually increasing debility and occasional pain in the region of the spleen, followed later

by great anæmia with enlargement of the spleen, progressing to profound cachexia and death from asthenia. Sometimes there are hemorrhages, and in Dr. West's case these came on early and a hæmophilic condition ensued. There was also œdema of the larynx necessitating tracheotomy, but the operation wound did not heal, oozing continued, and at length hemorrhage was sufficient for blood to be sucked into the air passages and prove fatal. At the post-mortem the liver weighed ninety-three ounces, the spleen seventy-six. The latter was soft, and one infarct was found with a state of slight cirrhosis. Both these organs are usually in this state. Some cases are said to have been benefited by arsenic. The spleen has been removed for this disease by Sir S. Wells and by Mr. Gould, who gave an outline of his case and thought the operation a justifiable one. A case of the disease in a girl of thirteen was mentioned, one in a boy of sixteen, another in a boy of ten. But there seemed to be some doubt about the last two. As the disease is rare and resembles the effects of malaria as well as cirrhosis of the liver, the diagnosis is difficult and not to be made without examination of the blood. Dr. Kanthack insisted that the blood should be examined in all cases of anæmia in order to obtain a more extended standard for comparison. The examination should not be confined to counting corpuscles and estimating hæmoglobin, but the different stains introduced by Ehrlich should be used to distinguish the several forms of leucocytes. Von Limbeck has suggested that splenic anæmia is only the last stage of the severe anæmia of rickets or of syphilis, and some of the cases seem to support the suggestion, while others are scarcely compatible with it. Those which have recovered should be particularly scrutinized in these respects, as should also those in which no post-mortem has been obtained. Besides splenic anæmia, the terms splenic cachexia, splenic pseudo-leukæmia, lymphadenoma splenica, spleno-mégale primitive, etc., have been applied to these cases.

I need only mention the splendid celebration of the jubilee of Lord Kelvin's work at the Glasgow University. The feats of the telegraph on the occasion will have familiarized your readers with the event and most of its interesting features.

The jubilee of chloroform is talked about as a suitable celebration for next year, but no active steps have been taken to organize it, and the question would be raised, why not make it embrace all anæsthetics?

Hospital Sunday has passed. Up to last night nearly £17,000 had been received at the Mansion House. This seems small compared with last year's total, but it is not without promise; for up to the same time last year the amount actually remitted was less by some £2,000. We must wait till the later amounts come in to make a profitable comparison.

Sir T. G. Logan, K.C.B., honorary physician to the Queen, formerly director-general of the army medical department, died on the 11th inst., aged eighty-seven. He had a very distinguished career and received many honors. He was a *persona grata* in regimental and official life, a genial companion, able administrator, and shrewd observer.

Fractures.—Having had some experience in malpractice suits, I make it a rule to give my patients with severe fractures a worse prognosis than I really expect and I always have witnesses to this. To the laity all fractures are alike, and because "Dick" had a broken leg which united perfectly, "Tom's" leg, which was fractured in the same place, must necessarily also become perfect. If this result is not reached, it is due to the doctor's ignorance or carelessness.—DR. KURTZ, *Southern Cal. Pract.*

OUR PARIS LETTER.

(From our Special Correspondent.)

SALTS OF COPPER AS COLORING MATTER IN CANNED VEGETABLES—DAMAGE TO PUBLIC HEALTH CAUSED THEREBY—PROTEST AGAINST USE OF—FOREIGN MEDICAL STUDENTS AND DOCTORS IN PARIS—GOVERNMENTAL MEASURES REGARDING THEM—THE PRACTICE OF MEDICINE—INTERNATIONAL CONGRESS OF SURGERY—INSTITUTE PASTEUR—LABORATORY APPROPRIATION, ETC.

PARIS, June 20, 1896.

THE addition of the salts of copper to vegetables sold in cans, in order to impart to them a brilliant green color, is always deleterious to the public health, and although many, perhaps the majority, escape any direct evidence of harm—such as epigastric pain, intestinal paroxysms, diarrhœa, colitis, etc.—yet mischief is done all the same; not so much because the salts of copper are cumulative, which they are only in an exceedingly small degree, but because of the effect upon the mucous membranes, which in very healthy persons may resist for a long time but finally yield to the constant irritation caused by their prolonged use. When green vegetables are cooked they assume a yellowish tint; yellow from an æsthetic point of view is certainly preferable to green, and from a physiological one less dangerous to health. It appears that manufacturers of canned vegetables in France are authorized to prepare their goods with the addition of a certain quantity of the salts of copper, which the public ignores, and Professor Duclaux, professor of biological chemistry at the Faculty of Sciences of Paris, expresses an official opinion that the public should be more thoroughly warned against the use of canned vegetables, and that the consultative committee of hygiene should obtain from the public authorities a decree in these terms or their equivalent: "The salts of copper are too little dangerous to prohibit their use altogether, but manufacturers who employ them do so upon their own responsibility, and all the accidents caused by their products are to be placed to their account, even though it be demonstrated that the can that caused them did not contain more copper than other cans remaining inoffensive."

It is to be hoped that the campaign so well begun by Professor Duclaux may be carried to a successful issue, with decided benefit to the public; it is rather remarkable, however, that while upon the subject, no mention was made of the many cases of lead-poisoning that may be and have been caused by canned vegetables and fruits, leaving coloring matter entirely out of the question, and attributable to the metal of the can itself.

At a recent meeting of the Chamber of Deputies, in reply to a communication addressed to him with reference to foreign medical students, the minister of public instruction replied in the following sense: The law of November 30, 1892, regarding the practice of medicine in France, having given rise to some errors concerning the obtaining of the degree of doctor in medicine by foreign students, the government has taken certain measures to remedy them. Nevertheless, it is important to respect the international conventions or agreements relative to this question.

There are actually in the different faculties of medicine of France at present ten hundred and fifty-four foreign students, or twelve per cent. of the total number of medical students. The greater part of these foreign students belongs to Russia, Roumania, Bulgaria, and Greece. England and the United States furnish the smallest contingent. It will be observed that all of these countries, with perhaps England as the only exception, are born to political and scientific

life more recently than France, the presence of these foreign students in French faculties being, therefore, an evident proof of the superiority of French instruction. To close the doors of our establishments to them would be a mistake, for most of them come to France only to pursue their studies, and, these terminated, they return to their native countries. The minister, in terminating, announced that he was devising a means to deliver to foreign students not provided with French qualifications, and having terminated their studies, a special diploma of doctor in medicine, not carrying with it the right to practise on French territory.

After this reply of the minister, Professor Lannelongue, the eminent surgeon, proposed a resolution, which was accepted by the government, inviting the minister of public instruction to depose a project of law upon the situation of foreign doctors and medical students in France.

To obtain the right to practise medicine in France, foreign students, and doctors of other faculties as well, will probably in the near future be obliged to become naturalized Frenchmen, to serve in the army, and pass all the regular examinations at the school of medicine besides. On these conditions the medical schools of France are open to the students of all countries. This sounds very liberal, but when read thoughtfully, and taking into consideration the fact that a thorough knowledge of the French language is also requisite and necessary, the already existing difficulties are only multiplied and amount practically to exclusion. Very few young Americans desiring to establish themselves in Paris would, if they could accomplish it, be willing to comply with all these requirements, and older members of the profession would not think of it.

The Faculty of Medicine and the profession at large are taking much interest in a project which also touches the American faculties and profession in general as well; namely, the organization of an international congress of surgery, that shall hold sittings at regular intervals in the four following countries: Great Britain, the United States, France, and Germany. The official languages of the congress shall be French, English, and German, and the first international reunion of surgery will take place in London, in 1900.

A movement against the Institut Pasteur has been started by certain interested parties, who accuse the successors of Pasteur of transforming the institute into a shop. It seems that to-day the important matter is not whether the serum is good or bad, whether the discovery is real or only illusory, but whether the Institut Pasteur, that pious monument to public charity, does not inconvenience by its radiant expansion a host of pharmacutists and small dealers in medical wares. It should not be forgotten in this connection that Dr. Roux, who recently received from the French Academy a prize of 25,000 francs, gave the whole of it, from the first sou to the last, to the Pasteur endowment fund. It would seem that inoculations, although they may cure hydrophobia and diphtheria, are powerless against envy and greed of gain.

The 250,000 francs appropriation for laboratories is, after all, not going to be had without some opposition and wrangling. Dr. Bourgoïn, in a speech made by himself in the Chamber of Deputies a few days ago, remarked that in his opinion the laboratories have been well endowed during the last few years. He continued: "When I made my experiments with our masters, Claude Bernard, Wurtz, and Berthelot, the government provided its laboratories liberally with long tables, chairs, blackboards, fountains, sinks, etc. As professors (*agregés*) we received 500 francs a year: that salary is now augmented to 3,000 francs in Paris and 4,000 francs in the provinces. As regards the regular professors, they receive at present from

6,000 to 9,000 francs in the provinces, and from 9,000 to 15,000 francs in Paris." Dr. Bourgoin thought that under the circumstances those who wanted to make individual experiments ought not to demand anything of the government.

The appropriation, however, is likely to be made. It is strange how easily doctors become politicians immediately after or even before election, and how willing they are to vote for measures oppressing their own profession.

GONORRHOEA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Dr. Herbert J. Hopkins' paper in to-day's issue cannot fail to interest the profession everywhere, as it presents a consensus of the current opinions on the treatment of gonorrhœa.

The doctor's elegantly written paper, however, contains some points on which we do not fully agree. The salient ones of these are in his comparison of gonorrhœal ophthalmia and gonorrhœal urethritis. While indisputably there is no difference in their pathology, the organs affected differ so widely in a mechanical sense that the same treatment may not apply to both. But I will not presume to discuss eye-affections, on which the author is certainly better informed than I.

Dr. Hopkins will not take it amiss that observation of the work of others and experience in the treatment of gonorrhœa have given me views diametrically opposed to his. I may sum them up as follows:

1. Gonorrhœa is not a self-limiting disease; if it were, we would not have that army of chronic gonorrhœas, which the treatment advocated in the paper under discussion has failed to affect.

2. It is not "impossible to shorten the course of gonorrhœa."

I have the records of a large number of acute cases, treated according to the formula published in the *Clinical Recorder* for February, 1896, which show complete disappearance of the discharge within ten days. I have now the records of twelve cases in private practice, cured within three days. All these cases, of which I have preserved the microscopic slides, show gonococci in profusion. I call them cured: (a) because curetting the urethra and examining the product revealed the absence of bacteria; (b) because strong irritant injections of nitrate of silver made a week later produced a discharge which contained no gonococci; (c) because large quantities of beer drank two weeks or twenty days later produced no discharge; (d) because sexual intercourse three weeks or thirty days later produced no discharge; (e) because urethroscopic examination showed a perfectly healthy urethra.

The above I attribute to careful, judicious employment of urethral and intravesical irrigations with graduated dilutions, mainly of potassic permanganate, and no other medication whatever. I even allowed those accustomed to it to drink a glass of claret at meals.

In chronic gonorrhœa—I mean true gonorrhœa with myriads of gonococci but uncomplicated—I have had as favorable results with a variation of the method published in the *New Albany Medical Herald* for November, 1895. I may cite a typical case: A physician of more than average good repute had for twelve years been "curing" his gonorrhœa on the plans so aptly recorded by Dr. Hopkins. His thick, greenish-yellow discharge was full of pus cells containing gonococci and the other microscopic concomitants of gonorrhœa. In five days the gonococci disappeared, three days later he discharge that had become muco-serous, ceased, and six months later—on Christmas Day—the

doctor insured me a substantial "morning drop" for the rest of my life, in the shape of a handsome diamond pin.

The MEDICAL RECORD for August 5, 1895, did me the honor to publish my paper on "Urethroscopy in Chronic Urethritis," in which this matter is more fully discussed.

As to the use of balsams: I showed them to be excellent culture media for gonococci in bacteriological investigations made in Berlin in 1894 and 1895. Of these a preliminary note was published in Pick's *Archiv* (Vienna and Leipzig, August, 1895). I hope to publish the paper in full in English, detailing the methods employed and the results obtained.

The author says: "During the first three weeks, the physician is indeed worthy of his hire who insures to his patient comfort and freedom from some one of the following complications: Balanitis, phimosis, paraphimosis, follicular abscess, lymphangitis, bubo, cowperitis, prostatitis, cystitis, epididymitis."

There are now, according to the above, one hundred and forty-two physicians in the United States worthy of their hire, not to mention Felike of Buda-Pest, Janet of Paris, Frank of Berlin, Goldberg of Cologne, and others in Europe.

My own experience since December, 1894, runs between twenty and twenty-five cases daily in private and dispensary practice. In not a single instance was the patient ever otherwise than comfortable after the first irrigation, and not a complication ever resulted.

George Knowles Swinburne has an experience almost double mine within the past twenty-seven months. He reports only one case of epididymitis, which he does not attribute to the irrigations.

These hasty notes are not penned to attack Dr. Hopkins, but in the hope that he may be led to investigate the treatment of gonorrhœa by hydrostatic irrigations. Then another far more able pen than mine will advocate them to the benefit of suffering humanity and the medical profession everywhere.

Through such writings haphazard will give way to the true scientific treatment of gonorrhœa.

FERD. C. VALENTINE, M.D.

242 WEST FORTY-THIRD STREET, NEW YORK, May 22, 1896.

The Waning Reputation of Colorado.—It was some time ago intimated in an Eastern paper that the streets of Denver were covered with the sputa of consumptives. The statement was not far from the truth. Unless very rigid measures for the prevention of the spread of consumption in Colorado are adopted and put into force, Colorado will become a "pesthole." One thing that may help us out in this country is the fact that the amount of rainfall seems to be on the increase. There is no question that Colorado has probably the greatest climate in the world, all things considered, for the average consumptive, yet, in our opinion, it would be a fortunate and glorious day for Colorado to lose that reputation. With a better understanding of the cause of consumption and better knowledge of its prevention and better facilities and methods for its treatment, climate will not long, we trust, be a desideratum in the management of this disease. We now look upon tuberculosis and realize that it is the most contagious of all diseases known to humanity. Every consumptive who walks along one of our sidewalks and deposits a lump of tuberculous matter, loaded with consumptive germs, is deliberately and, in most instances, intentionally doing that which will spread the very disease of which he is dying, and it was through just such criminal carelessness of some other consumptive that he contracted tuberculosis himself.—*Denver Medical Times*.

New Instruments.

A NASAL BAG.

By W. FREUDENTHAL, M.D.,

NEW YORK.

THIS small apparatus which I take the liberty of showing to you is intended to serve a double purpose. In the first place, it aids in controlling nasal hemorrhage. In an article on the etiology of post-nasal catarrh,¹ I have tried to show that in this city during the winter there are quite a number of hemorrhages from the nose which originate in consequence of the extraordinary dryness of the air in our rooms. I have experimented and find that at times we have as little as eighteen to twenty per cent. relative humidity in our houses. This lack of moisture has the effect of drying the nasal mucosa, which becomes cracked and frequently bleeds during the continuation of this drying process, which is induced by our artificial system of heating. Now, our text-books advise us to stop nasal hemorrhages by cauterizing the so-called locus Kieselbachii or any other affected part. However, if we take into consideration the etiology of the cases just mentioned, it will be evident that such treatment will render a mucous membrane which is already dry still more so. Therefore such patients have to return to the physician, until under more favorable climatic conditions the hemorrhages stop of themselves. Although such patients should have a course of systematic treatment, it is well to give them a means of stopping epistaxis at home or on a journey. For this purpose I believe this apparatus will be of good service.

It consists (see Fig. 1) of two equal-sized rubber bags, *A, A*, which are connected by a rubber septum, *s*. On the upper part of each bag there is an opening that is closed by a screw, *a*. Through this opening the bag can be filled with ice or anything else. The apparatus, therefore, consists of nothing more than two ice bags connected with each other. These bags are filled, put on the nose, and fastened around the head with the two bands, *C*. The apparatus is manufactured in three sizes by Messrs. George Tiemann & Co.

FIG. 1.

It will be advisable always to take that size which leaves open the introitus narium, at the same time, however, covering the whole external nose. The nostrils are to be left open for the purpose of plugging the nose. It is not at all objectionable that the bag should cover part of the forehead. But it will usually extend above the eyes, and for the protection of these organs it is best to cover them with some cotton.

I have repeatedly been called in consultation by colleagues in severe epistaxes, and I have always succeeded with comparative ease in controlling the hemorrhage. As a matter of precaution I invariably plugged the anterior nares, but each time I had the feeling that the ice bag had helped me essentially. During these manipulations the patient generally sat before me, either in his bed or, still better, on a chair.

In different operations under general anæsthesia I have used the ice bag as a prophylactic measure.

¹ Demonstrated before the physicians of the German Poliklinik, January 17, 1896.

² "Some Points Regarding the Etiology and Treatment of Post-Nasal Catarrh, with Remarks on the Hygiene of the Respiratory Organs," Journal of the American Medical Association, November 9, 1895.

Thus, I applied it three times during Ash's operation for deviation of the septum, and in other operations on the nose in which a severe hemorrhage was to be expected in plethoric or anæmic subjects. The bag was put on the nose as soon as or before narcosis was begun. It appeared to me that by the time anæsthesia was established the effect of the ice could be noticed. But my experience in this respect is too limited to allow any conclusions.

On the other hand, my extensive experience in stopping nasal bleedings of other kinds by means of this apparatus has convinced me that it is a positive help.

This apparatus serves also another purpose, *i.e.*, to abort acute coryza. In acute colds heat is found beneficial in other parts of the body, and, reasoning from this experience, I have applied hot water to the nose in this bag. The patient lies down and changes the water as soon as it begins to cool.

In addition I ordinarily use the small receptacle, *B* (see Fig. 2), which can easily be fastened to the bags.

FIG. 2.

This helps to approximate the bags to the nose and will hold any medicament the physician chooses to use for inhalation. Thus, I have applied camphor or menthol in substance or in oily solution on cotton. These substances are thus inhaled constantly through the perforated roof of the receptacle, while at the same time, of course, the hot-water bags lie upon the nose. In this manner I have made it possible for some singers who came to me in the forenoon with a bad cold to use their voice in the evening. In other cases I have also had good results with this method, and I can therefore recommend it as a convenience to the profession.

943 MADISON AVENUE.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 4, 1896:

	Cases.	Deaths.
Tuberculosis.....	191	127
Typhoid fever.....	21	3
Scarlet fever.....	73	9
Cerebro-spinal meningitis.....	2	2
Measles.....	160	11
Diphtheria.....	231	39
Small-pox.....	0	0

Enuresis.—According to Foster's "Encyclopædic Medical Dictionary" we have:

Enuresis atonica—Enuresis from debility.

E. continua—Incontinence of urine both day and night.

E. diurna—Incontinence of urine by day.

E. irritata—Enuresis from irritability.

E. mechanica—Enuresis from mechanical causes.

E. nocturna—Nocturnal enuresis.

E. paralytica—Enuresis associated with paralysis of bladder.

E. spastica—Enuresis due to spasm of bladder.

INSANITY OF PUBESCENCE.¹

By HIRAM ELLIOTT, M.D.,

WOODHAVEN, N. Y.

OF the insanities occurring at various periods of life the study of none is so interesting and instructive as that of the forms occurring in youth. All ideation is then much simpler, the brain cells being receptive rather than elaborative. Little or no effort is made to analyze or conceal the ever-changing emotions, and, the inhibitions and judgment being comparatively undeveloped, ready utterance is given to every thought. Cerebral states are more frankly manifested. Hence, when conditions of mental alienation arise, not only are they less complex, but they are reflected more directly from the underlying lesions, being less refracted by individual characteristics or dimmed by inhibitory power. In other words, the mental machinery is less intricate, and therefore more easily understood, and any defects in its action are more readily seen and appreciated.

All healthy growth or discharge of function is attended with the sensation of pleasure. It is the privilege of the healthy, normally developing youth to enjoy the height of human felicity. Not only are his recuperative tendencies at their best at this time, but he is passing through his constructive stage in the strictest and highest sense of that term, and every day is adding to his mental and physical strength. And when nature awakens in him the procreative function she endows him with a new element of power, and adds another attribute of physical perfection.

It is perhaps not too much to say that, physiologically at least, the chief end of man is to perpetuate the species, and that to the procreative function, and to foster the results of its healthy and legitimate activity, all other functions are subservient. Indeed, nature is so jealous of this power that she usually denies it to idiots and others incapable of rearing offspring, and allows it to exist in the human subject only during the best years of life. And if by chance or design the organs in which it is seated are removed before maturity, all the manly and womanly characteristics, having then no purpose to subserve, fail fully to develop, and the individual becomes the merest caricature of what he might have been.

The grave constitutional symptoms often caused by slight lesions of the genito-urinary organs are further proof of their intimate and extensive relation with other parts of the body. For example, the simple gentle passage of a soft bougie into the bladder may quickly give rise to a violent chill attended by intense prostration, alarm, and anxiety, accompanied by violent vomiting, profuse diarrhoea, coldness, and lividity of the surface, almost total suppression of the urine, all the evidences of uræmia, and a rapidly fatal issue (Keyes). A slight blow on the testicles has caused unconsciousness followed by vomiting and prolonged and severe prostration. Indeed it is within the range

of possibilities that an injury to the organs of procreation may produce a more serious effect on the mind than an injury of the same extent to the brain itself.

Such then being the importance and sensitiveness of these organs, the question of their condition is of the greatest consequence in the study of the disease incident to youth in both sexes. For, whatever may be the cause, youth is beset with many ills. Especially are neurotic and catarrhal conditions prevalent. So many fairly healthy children at fifteen or sixteen become skinny and nervous, and develop chorea or epilepsy or insanity, that we are forced to the conclusion that causes both common and powerful have come into force; causes with an essentially destructive tendency, decreasing the resisting power of the individual, encouraging the appearance and growth of hereditary taints, and often temporarily and even permanently arresting the mental and physical development, and blighting the entire organism. It must have come within the experience of most physicians to see the previously healthy children of certain neurotic parents one by one fall a prey to some nervous or physical disorder when they reach this critical stage of their life.

It is maintained that at puberty sexual ideas and promptings, suddenly forcing themselves upon the mind, precipitate a sort of chaos; that the assimilative apparatus being no longer able to meet the extraordinary demands of the organism, chiefly in consequence of the newly acquired function, the body falls into a state of malnutrition. This explanation is both inadequate and illogical. Indeed it is in cases in which the procreative power is lost that the peculiar stunted physique is most typically seen; and the more nearly the procreative function has been extinguished by early and excessive abuse of the sexual organs, the more nearly does the physique conform to this type. On the other hand, the sexual longings are usually weak or wanting in the insane pubescent, there being rather an aversion to and an intense antipathy for the opposite sex in every way. That accumulation of sexual energy which normally gives rise to sexual promptings does not obtain, but in its place is found a condition of sexual irritation, which impels the unfortunate individual to degrading habits, and even to acts of indecent assault. These conditions may exist in children long before they are capable of a sexual idea. Not a few children of both sexes, either by accident or by imitating their companions, learn evil habits which induce in their generative organs such debility that when they arrive at the age of puberty they seem incapable of natural sexual promptings. Sexual longings are normal in the pubescent, and the only question of consequence regarding them is, will they provoke their unnatural gratification?

That they too frequently do is beyond peradventure. And if the organs misused are so sensitive, it seems to me idle to shut one's eyes and try to explain the somewhat rapid increase of insanity after the onset of puberty by profound psychological discussions regarding the intricate reactions between the mind and body, or regarding mental conflicts between the youthful and adult traits and propensities, relegating the habit in question to the category of symptoms. To me it is

¹ Read before the Brooklyn Society for Neurology, December 26, 1895.

evident that neither body nor mind can develop normally if kept in a state of weakness and irritation by the excessive practice of an exhausting habit. I do not wish to seem to dwell unduly upon this disagreeable topic, but I cannot avoid a matter because disagreeable which it behooves every parent and physician to look squarely in the face.

Forms.—In the insanities occurring in the period in question there is not that tendency to conform to type that is seen in adult life. The same may be said of the normal mind in youth. The individual characteristics, which when once set give color to and modify the symptoms of all diseases, are just being moulded from the still plastic material. Every one accepts the dogma that insanity is a clinical expression of brain disease; but no one has so far succeeded even in demonstrating a pathological difference in cerebral conditions to correspond to the symptomatic difference between mania and melancholia. Even in paresis, in which the pathological findings are comparatively so constant and definite, the scalpel and microscope have not revealed why one victim should seem supremely happy and another wholly miserable. The study of etiology is equally unsatisfactory, identical causation being found capable of producing symptoms most unlike. The physical vulnerability and potency of the individual seem to be capable of directing etiological factors to the production of certain pathological states, and the individual temperament to be able to modify and give color to their clinical expression. An insane man is the caricature of himself in health. Insanity is mental derangement in the strictest sense of that term, and out of the resulting disorder propensities and characteristics, hitherto existing but more or less held in abeyance, possibly in an exaggerated form, come to the front and predominate. And often they have not very far to come. In youth, even in health, we find little that is fixed—the purposes, the emotions, the moods are ever changing, and when conditions of mental alienation arise, we find naturally the most widely differing phenomena even in the same individual. Sometimes, however, we find instances of quite typical maniacal or melancholic perversion in youth, but investigation will show a correspondingly well-defined temperament and character, and the absence of masturbation.

In childhood insanity is expressed almost wholly in conduct. Occurring as a pure insanity, perhaps only in children who have practised masturbation very early in life, there is not much mind to be affected. These puny unfortunates have the pasty face, sunken eyes, and unhappy expression, widely dilated pupils and exaggerated reflexes which indicate an exhausted and hypersensitive nervous system. Intense restlessness, sudden fits of anger with homicidal tendencies, wanton destructiveness or cruelty, great timidity, lack of memory and that curiosity which is so strong in healthy children, irregular sleep, and capricious appetite are some of the phenomena observed. Two boys whom I saw in my hospital service, aged thirteen, but looking more like children of seven, were so maliciously destructive, and so wholly ungovernable in the children's wards, that they had to be sent to the adult male ward for management. They were silent and uncommunicative, and when spoken to paid so little heed that it was difficult to tell whether they understood what was said to them or not. Another boy whom I saw a short time ago, aged fourteen, but looking only ten, who had masturbated since four, was so nervous that a single sharp question made him bellow with fear, and so interfered with his co-ordinative power that he could scarcely articulate, and could not walk across the room without fouling with the furniture. His brain seemed little more than a hypersensitive reflex centre, from which all ingoing stimuli re-

issued at once without elaboration or inhibition in expressions of fear, very much as they might have done fourteen years before when he was an infant in his mother's arms. In this failure to understand my advances, and the tendency to regard them as necessarily hostile, are seen fundamental principles in the development of a delusion—more or less distortion of ingoing stimuli by the representative apparatus and their subsequent misinterpretation in terms of a predominant emotion or idea.

Advancing a few years, when purely mental phenomena begin to come into prominence, we find the symptoms still more mixed and varied. One day the manifestations may be characterized by great exultation, the next by depression, and the next by stupor. Seen at one time the patient presents intense motor excitability; the next day he may be cataleptic. Some trivial remark causes first immoderate laughter, and then tears or anger. The reflexes are much exaggerated and the whole economy in a state of irritability. Delusions may be vague and indefinite, or well marked, and vary from the most ambitious to the most depressing or persecutory type. One lad of seventeen when first seen was rushing up and down in the most abject terror. In a few days he was cheerful and so apparently well that he was sent to do some light work. He began the day by assaulting his attendant; he next made an attempt to escape, and was returned to the ward in a very elated condition. The next morning he was cataleptic and remained so for weeks.

Coming down into the adolescent period when mental manifestations come still more to the front and predominate, insanities become more typical. Some individuals are adult at twenty with well-marked mental and physical characteristics, and in such, especially if not addicted to bad habits, we may have typical melancholic and maniacal perversions. Of course the results of the undeveloped brain, such as cretinism, idiocy, and its cousin, paranoia, which manifest themselves in all periods of life, are not referred to above, nor are they discussed in this paper. And it is proper to remark here that it is possibly this lack of conformity to type that has given rise to the term insanity of pubescence, as though it were a distinct variety of alienation; but it must be seen from the foregoing that the forms in question have rather a coincident than an intrinsic connection with pubescence itself.

Causes.—In nearly every case of insanity in youth heredity is an etiological actor. The fact is hard to get at sometimes, owing to the dislike most people have to discuss any weak points in their family. One woman positively denied all neurotic conditions in the family history of her insane adopted daughter, but a reliable friend of the patient informed me that the girl's mother was epileptic and her father paralytic. An excellent family history is often obtained from parents who are themselves walking demonstrations of its incorrectness. Some obliging old lady, who has known the family for years, will know about any nervous, or hysterical, or consumptive, or dissipated, or epileptic, or paralytic, or insane members of the family, or any intermarriage of cousins, and will contribute largely to the evidence that insanity in youth is strongly hereditary. But then, judged by its worst branches, what family tree is sound?

Again, the bringing up of many children strongly predisposes them to neuroses of all kinds. It is an unfortunate circumstance that parents who beget neurotic offspring generally add to the evil by bringing them up badly. Next to the stamp of heredity, comes the impress of the environment as an agent to mould the character and determine the tendencies of the individual. Hot-house methods are much to be deprecated. Abundant contact with moral, healthy, happy

people of both sexes and of all ages is an essential condition to the proper development of a youth, and no parents, neurotic or otherwise, can grossly neglect this principle without imperilling the mental health of their children. Every physician of experience with insane youth must recall how large a proportion of his cases have a history of being quiet and home-keeping youth and the fact of their avoidance of the opposite sex put forward as evidence against vicious habits. The cigarette-smoking imp of the street, exposed to so many pernicious influences, is one extreme, and this pampered home-keeping youth is the other, and so far as his health is concerned possibly the worse extreme. A human being is a dangerous animal to be left too much alone with himself.

Of the exciting causes of mental alienation in youth, masturbation stands first. How any one with any experience with insanity, and who has kept his eyes open, can hold any other view is most surprising to me. Not only may this vice cause insanity in youth, but it may cause it in adult life, and addiction to it aggravates the symptoms and lends gravity to the prognosis in any case, and is one of the most potent causes of chronicity in the insane. It operates in three ways. First, it has an irritant and debilitating action on the brain and spinal cord, and through these upon the entire organism; then it may produce disorders of the genital organs, such as spermatorrhœa or leucorrhœa, which add to and perpetuate the direct results of the habit; and, third, there are the effects of that hidden strife betwixt shame, repentance, and good intentions, on the one hand, and irritations which imperiously impel to the act, on the other, which are probably even more pernicious than the primary direct and physical effect (Griesinger). True, the habit may be the result of insanity, especially among those confined in institutions and thus cut off from opportunity for sexual intercourse. I have seen numbers of such cases, and with the commencement of the habit the mental manifestations became more intense, proving beyond a doubt that a new and powerful factor had come into operation. Other causes are ill health and overwork, operating chiefly in adolescence, intemperance and excessive use of tobacco in a few cases, trauma and shock, grief and disappointment.

Prevalence.—Insanity before seventeen of such severity as to send the patient to an asylum is rare; the vast majority of cases under twenty-one come after seventeen. The reason is not far to seek. Youth is a very recuperative period, and nature repairs injuries very rapidly at this time. The struggles of life with their accompanying disappointments have scarcely been undertaken. The manifold dissipations have hardly been learned, and of course their effects not felt. Childbearing with its train of ills, and the degenerative changes of later life are unknown quantities. Clouston says that only 0.9 per 10,000 of the general population under twenty are sent to asylums in England and Wales each year, while the proportion over sixty is twelve times as great. In the State of New York the total number of patients of all ages admitted to the public asylums during the five years ended September 30, 1893, was 22,231, while the number under 21 was 1,086. But there are more persons under 21 than over, therefore insanity is more than twenty-one times as frequent after 21 as before. Again, the number between 15 and 20 was 1,006; between 20 and 25, 2,252; 25 and 30, 2,992; 30 and 35, 3,044. In other words, speaking roughly, insanity seems to be twice as frequent between 20 and 25 as between 15 and 20, and three times as frequent between 25 and 30. Again, it is found that of those admitted under 20, at least one-half are between 18 and 20. So we see how small a number become insane within four years, say, of puberty—about 500 out

of 22,231. It is proper here to remark that the onset of puberty cannot be a very strong exciting cause of insanity, when with all other causes the result is comparatively so small. The next two or three years are the student and initiative years of life, and if the unfortunate youth's constitutional powers have been weakened by faulty bringing-up or bad habits, it is a very precarious period. How precarious may be guessed by the fact that at least one-half of all cases of lunacy occurring under 21 arise in these years.

Course and Symptoms.—It would seem that all forms of insanity are ushered in by a longer or shorter period of depression, and the forms in question are no exception to the rule. Restlessness, sadness, irritability, taciturnity, and loss of interest in surroundings are among the symptoms first noticed. The physique of our unfortunate patient in many cases becomes peculiar and instructive. Puny and thin, he looks blighted. He seems to have stopped growing, and he carries into adolescence the appearance of a child. His face is pale and pinched, his eyes sunken, watery, and shifting. The cold, clammy hands are thin and clawlike; the skin soft and delicate. The development of all the tissues, but especially that of fat and connective tissue, seems to have been hindered. The beard in males is weak or wanting, and the busts do not fill out nor the hips widen in females; the voice remains shrill and childish. And it is the operation of that cause that is able to lay such a blighting hand on the body, that produces that exhausted and irritable condition of the whole nervous system, which is so disastrous that its clinical expression is insanity.

After the period of depression has existed for a time, the multifarious symptoms of which I have spoken appear. From the profoundest stupor to the most intense excitement; from the most stubborn silence to the wildest raving; from the pleasantest mood to the most hostile impudence; from boisterous laughter to the bitterest weeping; many of the patients pass through the widest range of symptoms in an incredibly short time. On the whole maniacal perversions are thought to be most prevalent, and if noisiness and excessive activity be meant this is true. But according to my observation painful mental states are far the more common, if indeed they do not give more or less color to the phenomena in the majority of instances. Many cases indeed run into a quasi delirium which seems to be the expression of acute mental and physical agony—restless, sleepless, raving, refusing all food, emaciating rapidly, and often dying in spite of the best efforts of physician and attendant. In others the tendency is rapidly to dementia without great intensity of symptoms. In these cases the memory soon fails and the patient becomes solitary, unsociable, untidy and stupid, and soon sinks into fatuity. In others explosive symptoms continue for years with little change. Marked hallucinations of the senses develop and the patient passes a part of his time talking to himself or to his imaginary enemies. He is usually careless of his surroundings, given to fits of obscene and profane scolding, untidy and troublesome in almost every way. Some cases again run a very uneventful course, fits of sulking or crying, childish manner and talk, loss of memory and of interest in surroundings being the chief phenomena. Almost all insane youth have hallucinations, sometimes of all the special senses. Delusions, especially regarding poisoning, or contamination, or the condition of the viscera, or involving the belief that the patient has become angelic or divine, are very common. On the other hand these may be vague and changing or wanting altogether. One of the worst cases I ever saw showed neither delusions nor hallucinations, but spent her time raving and berating herself for yielding to her vicious habits. States of confusion, showing

marked failure of the normal association of ideas, and arising out of the exhausted condition of the brain, are so common as to be almost characteristic. Ecstatic, cataleptic, and katatonic states are frequent.

One peculiarity in all these cases is the tendency to sudden remission and exacerbation of the symptoms. A patient who was wildly excited a few hours before is often found apparently recovered. He admits he has been out of his mind, is thankful for what has been done for him, and talks and acts like a well person for days together, in the end to succumb to a second attack worse than the first. In insane pubescents not addicted to the habit of masturbation, this tendency is much less marked. In fact these cases usually run a more even course in every way, and especially are they more frank and tractable. In females the menstrual flow may be suppressed for months. Appetite is usually poor, as the result of delusions regarding poisoning or the condition of the abdominal viscera referred to above; or it may be due to the enervated condition of the stomach. The bowels, especially in females, are obstinately constipated, and in girl patients the persistent refusal to pass water may call for the services of the catheter.

Prognosis.—Clouston says that 51 per cent. of these cases recover. Bevan Lewis estimates that 73 per cent. get well. These figures, however, seem to me too high; they are certainly not borne out by the statistics of the public asylums of this State for the period mentioned above. From these statistics I find that the recoveries under 21 years of age amounted to 28 per cent. on the number admitted; between 20 and 30, 23 per cent.; between 30 and 40, 20 per cent. Even these figures are encouraging and, if they prove anything, they are evidence that mental troubles in youth are by no means hopeless, but that this is not only a resisting but also a highly recuperative period of life. Recovery is often complete and lasting. One of the best specimens of manhood, both mentally and physically, that I know, an able lawyer and mathematician, spent a short period of his youth in an asylum. Of those who do not get well, a small percentage dies of exhaustion or intercurrent disease. Quite a number so improve that they are able to be at home, and remain as a sort of warning to the other members of the family. The remainder, in different degrees of dementia, form rather a disagreeable contingent in asylum wards. The average duration of cases ending in recovery is from six to nine months.

Treatment.—One glance at our patient suffices to suggest the first principle of treatment. Nature has failed to make an adult of this youth chiefly because of the irritated and exhausted condition of his nervous system. Remove the irritation, if possible, and repair the exhaustion. Place the patient in quiet, pleasant, and healthful surroundings with plenty of sunshine. Ascertain if there be any tight prepuce, or phimosis, or short frenum, or congenitally small meatus urinarius, or vesical stone; any malformed clitoris, or pruritus vulvæ, or leucorrhœa, or cystitis, which by their irritation not only may cause profound reflex effects, but also keep the unfortunate youths' minds on their generative organs and thus provoke vicious habits. Remember that this habit may be carried on without manipulation and may exist, lack of evidence on physical examination, failure of the attendant to observe it, and the denial of the patient, notwithstanding. One patient of mine, seventeen years old, whom I brought through a severe attack of insanity, in whom no evidence of this habit could be found, afterward boasted to me that she had masturbated all through her sickness. To stop the habit, the removal of all provocations and careful watching are of the most service. Continuous exhibition of the bromide of potash, with the hydrobromate of hyoscyne in small doses,

seems to be of some use in alleviating sexual irritation.

To repair the emaciation in the milder cases, or after acute symptoms have passed by, the hot-spray bath twice or three times a week claims first attention for its soothing and stimulating effect. Exercise in the open air with tonics, especially strychnine and arsenic in small doses before meals, cod-liver oil in never more than teaspoonful doses, generous diet at absolutely regular intervals, and consisting almost entirely of milk, hominy, potatoes, and bread, with meat in small quantities, regulation of the bowels, not too much restriction of the patient's actions, and very few sedative or hypnotic doses seem to me to be the chief elements of good treatment in these cases.

In delirious cases, and others refusing food and medicine, resort must be had at once to the stomach tube. By this means not only may be administered medicine, but also that generous supply of food which is necessary to repair the extraordinary tissue waste, and which of itself is often more calmiative than any remedy. The staple articles to be given are milk and eggs, and occasionally broth or peptonoids. In cases in which the excitement is not very great a pint of milk, with two eggs, and two teaspoonfuls of whiskey, if there is any tendency to the typhoid condition, given three or four times a day, will usually be found sufficient. If the excitement is very great, and there is excessive muscular activity, the above amounts may be considerably increased. I have given four pints of milk so thick that it would just pass the tube, twelve eggs, one ounce of butter, and other necessary additions to a patient every day for weeks, yet diarrhœa was not set up, and only one or two feedings were rejected by vomiting. My patient lived and recovered her mind. In stuporous or cataleptic conditions the amounts must be much less or fatal diarrhœa may result. Ten drops of dilute hydrochloric acid added to each feeding will be of service. These patients should be kept in quiet surroundings but not left alone; they should be allowed to roam about practically unrestrained, encouraged to sleep at any time, and their noise should be put up with. If they go forty-eight hours absolutely without sleep, one-eightieth of a grain of hydrobromate of hyoscyne with one-fifth of a grain of morphine will usually secure a few hours' rest.

And here I must be allowed to say a word about the alkaloids of hyoscyamus. Hyoscyamine should not be used; hyoscyne, being more effectual and safer, because less stupefying and depressing, should always be preferred. Although not well borne by young or agitated persons, yet, if it becomes expedient to put an end to an attack of frenzy or to enforce sleep, this drug, either alone or in combination with morphine, is the best means at our disposal. For this purpose at least one-sixtieth of a grain should be given hypodermically, smaller doses usually making the patient worse. Great dryness of the throat, leading the patient to believe he has been poisoned, headache and dilatation of the pupils, muscular prostration, the production of hallucinations, or increase in the intensity of those already in existence, and a general feeling of unrest, are some of the disagreeable after-effects of its first administration. A few patients, however, soon learn to like the sensation it produces, and in these cases it is a very valuable remedy; calming the convulsions, securing sleep, depressing the sexual organs, stimulating the kidneys, and certainly not interfering with the action of the stomach or bowels. Others again, after its administration, pass rapidly into a sort of delirium with intense restlessness, weak and rapid pulse, flushing of the skin, and wide dilatation of the pupils. If sleep follows, it is short and unrefreshing, and the patient awakes in a worse condition than before. These effects, however, more rarely follow

the hyoscine and morphine combination referred to above. Before resorting to such powerful medication to procure sleep, all the simpler means should be tried. A hot bath, or a glass of hot milk to which has been added a tablespoonful of whiskey, sometimes proves effectual. I think physicians often get too anxious about this matter and employ hypnotics which sometimes do more harm than the insomnia. Especially is the routine use of chloral to be condemned. In most cases natural sleep will come unbidden, unless in the mean time the physician yields to the temptation to give his patient some powerful sedative for the sake of somebody else. In the treatment of very many of these cases the highest skill is patience.

The term insanity of pubescence has been used in this paper to include the aggregate of pure insanities occurring in youth. I have pointed out the difficulty encountered in classifying these forms according to present methods, and I must be allowed to express the conviction that there is no form of insanity so intrinsically connected with, or so essentially arising out of the pubescence itself, as to be well-named after it; and to venture the opinion that when alienists shall have discovered a rational basis of classification very little of our present nomenclature will pass muster.

RUPTURE OF THE PANCREAS.¹

By B. F. HADRA, M.D.,

SAN ANTONIO, TEX.

H. B.—, nine years old, an unusually bright and well-educated boy, riding a bicycle down-grade, was struck by the handle against the epigastrium on August 13, 1895, at 3 P.M. He fainted, vomited, but rallied fully in a short time. At eight o'clock he began to suffer from severe pain in the abdomen. He was seen at twelve that night by the family physician, Dr. Graham Watts, who relieved him by opiates. Dr. Watts watched the further developments expectantly as no distinct injury could be made out. The boy improved slowly, but did not regain his usual health. The most prominent symptom was his excessive and perverted appetite. He, for instance, could eat six or eight boiled eggs, detested table salt, and so on. On the 6th of September his mother noticed a swelling in the region of the stomach, and on the 9th Dr. Watts could make out an accumulation of fluid behind the stomach, which latter stood out in high relief with well-defined borders, resting on a dull area which extended on the right side to the angle of the ninth rib and on the left side into the thorax, so that the dullness over the liver and spleen was continuous with it. Also the transverse colon could be easily recognized by its prominent contour. Between it and the stomach was a zone of about one inch in width, giving dull percussion sound. The temperature was between 98.8° and 99.2° F. This condition justified the assumption of a pancreatic rupture with leakage into the cavity of the lesser omentum. The normal condition of urine and feces seemed not to militate against it. I fully concurred in this diagnosis, and on the 9th, with the good advice and assistance of Dr. R. E. Moss, an incision of about two and a half inches was made in the middle line so as to hit the interval between the stomach and transverse colon (Dr. Watts operating). There an area of about one square inch was raised and the omentum stitched to the parietal peritoneum on either side of the incision. Opening this area a clear limpid fluid escaped, looking like the white of egg, entirely free of bloody admixture, amounting to over a quart. The internal lining of the sac was smooth, shiny, and obviously constituted by the endothelial layer of the lesser cavity of the peritoneum. An introduced finger

could feel the pancreas deep down in the cavity. A drainage tube was inserted and the wound closed around it. The fluid, on examination, was found alkaline and changed starch readily into sugar. No further test was instituted, as there could not exist any reasonable doubt regarding the nature of the injury.

The patient suffered little thereafter. His temperature ranged between 99° and 101° F., as some inflammatory irritation of the sac soon set in. The limpidity of the secretion, which was very free, changed into a muddy, flocculent discharge, which excoriated the surrounding skin in spite of all kinds of precautions. The perverted and greatly increased appetite continued. Toward the 15th the temperature became normal and the discharge lessened considerably. On the 22d the boy was considered convalescent. The fistula had closed, and only slight superficial abrasions and excoriations had to be tended to. He was greatly emaciated, however; but from now on gained steadily and was bright and cheerful up to about the 10th of October, when the temperature rose as high as 103° and even 104° F. The bowels became constipated, and a very annoying sensation as of dragging on the stomach was a constant complaint. There was now a swelling noticeable under the right rectus muscle close to the upper end of the incision. As a small suppurating fistulous track was detected, apparently leading under the muscle, it was surmised that a stitch abscess had formed from one of the buried sutures. On the 12th we tried to remove this latter and to empty the abscess by inserting a grooved director and splitting the parts on it for about one inch. To our surprise we at once found ourselves in the abdominal cavity, encountering adherent and angry-looking omental fringes. They were detached and removed. Now, inserting the finger in the direction of the before-mentioned swelling, a smooth tumor of the size of a hen's egg was felt, situated between stomach and liver. Puzzled what to make of it, and not being prepared for a more extensive operation, we tried to clear up its nature by searching for a communication between it and the original fistula, but none was found. We left it undecided whether it was the gall bladder drawn over to the stomach by adhesions, or a partitioned-off portion of the omental sack, filled with pus or pancreatic juice. The boy, though, began to feel better at once; especially the dull dragging sensation in the abdomen disappeared entirely. Thus it became evident that the omental adhesions had caused the new trouble. The suppuration stopped, the temperature became normal, and only the irritated stitchholes claimed further attention. The tumor disappeared gradually. In a word, the patient recovered perfectly. He is now the picture of health, though a ventral hernia is threatening.

I would not expect the general practitioner, who, as a rule, deals little with rarities, to take much interest in this case, were it not that traumatism of the epigastrium, as from blows or falls, is very common. It must certainly be of great help to have before our minds all possibilities as to the nature and outcome of such injuries. From such considerations I collected what literature at my disposal offered regarding rupture of the pancreas, which, as I now think, is not the least common accident after blows and falls upon the epigastrium.

Before all, the differentiation between a real pancreatic cyst and an extravasation of pancreatic fluids into the lesser cavity of the peritoneum (the bursa omentalis) ought to be insisted upon. It looks like a matter of course; still there is a good deal of confusion to be found in many of the contributions on the subject, everything being termed a pancreatic cyst. There can be no doubt that a true cyst may be caused by traumatism, and almost all authors believe in such

¹ Read before the West Texas Medical Association.

an origin for a great number of their cases; because from contusion an intra-glandular thrombosis of vessels or ducts, or an intra-glandular hemorrhage may result and lead to the formation of a cyst. But it is equally evident that this is quite a different thing from a condition in which the walls are nothing else but those of the peritoneal pouch in front of the pancreas. The former formation is a true cystic tumor behind and under the peritoneum (retro-peritoneal) (Fig. 1). The latter is intra-peritoneal (Fig. 2). The former, there-

fore, having its own walls, lifts the peritoneum up and dips into the omental bursa, while the latter is the bursa itself. The former will vary in its pathological construction, being a retention cyst, or of a compound structure, perhaps malignant, containing a variety of solids and fluids; while the latter will be a more or less unchanged peritoneal pouch containing blood or pancreatic secretions, or both. In the latter instance the traumatism has simply produced a rent in the gland and, at the same time, in its peritoneal cover, so as to allow the fluids to pass through the slit into the cavity that lies in close apposition to the pancreas. Possibly, though, a real cyst may occasionally burst and the thinned peritoneal cover with it, so that the contents will be emptied into the omental bursa, in which case there will be a mixed condition; that is to say, a veritable cyst *with* an extravasation into the lesser cavity of the peritoneum (Fig. 3). However, I have not yet found a description of such an occurrence.

As to the differential diagnosis there will seldom be any difficulty. A real cyst is a more or less chronic, insidiously commencing growth, whilst in the other instance a recent traumatism is the beginning. A cyst will be a well-defined, rounded tumor, more or less movable as a whole, perhaps nodulated, rarely very large, following the movements of respiration; whilst the filled peritoneal sack will be a slack, elastic, fluctuating mass. The pancreatic cyst will be found mostly in the middle line above the umbilicus; sometimes a little to the left; while the other extends, according to the outlines of the bursa—in the beginning slightly perceptible but growing more and more in its area—from the right side over the gastro-hepatic ligament (about in front of the angle of the ninth or tenth rib) to the left as far as to the outline of the gastro-lienal and pleuro-colic ligaments, that is, as far as the anterior axillary line, and upward under the left brim of the thorax, so that the dull area will indefinitely reach up to the right and left lobe of the liver, to the spleen, etc. Thus the dulness on percussion will extend farther to the left than to the right. Perhaps also in the back a dull area will be detected, as in one of Lloyd's cases, in which it extended from the angle of the left scapula down to the lowest ribs. The apex beat may also be raised to the left.

In either instance the tumor lies behind the stomach and the transverse colon, though a cyst may work itself between both, lifting up the gastro-colic ligament. On percussion in either instance the tympanitic

sound of stomach and colon will be made out, and if any doubt exist, both ought to be inflated by the usual means. But with a cyst only in extreme cases will both hypochondriac regions be occupied, while otherwise the tympanitic areas will appear like islands on a general dull basis. The interval between stomach and colon, the site of the gastro-colic ligament, will in a distended bursa form a dull zone, because here the fluid reaches up to the omental front wall. With a cyst this zone will not be more detectable than under normal circumstances, except the tumor has gotten into this space, when it will easily be recognized as a tumor. I may at once say that this place ought to be selected for probatory puncture.

However, the origin of the omental accumulation may not be pancreatic at all. Evidently hemorrhage from any vessel within the omental sack may cause an accumulation of blood, so that a correct diagnosis may be impossible. An exploratory puncture will clear up most of such cases. Whenever the fluid, so gotten, offers the features of pancreatic juice, that is, if it be more or less like the white of an egg, or if it chemically shows the attributes of pancreatic secretion, the case is, of course, decided. If, on the other hand, the contents should be a mixture of blood and some other fluid which is lighter, that is, if the contents be thinner and lighter than pure blood, it is almost certain that there exists leakage from the pancreas in addition to hemorrhage, because there is no other fluid that could be extravasated in this region, except chyle, which occurrence is still rarer. Only if apparently pure blood is found, an uncomplicated injury of some blood-vessel within the lesser peritoneal cavity has to be looked for. From experience and from the result of Senn's experiments, we know that rents and ruptures of the pancreatic gland are not accompanied by much hemorrhage—in one case there was none at all—but then the large pancreatic vessels themselves may have been ruptured. For the sake of illustration I will cite one of J. Lloyd's cases,¹ who deserves all the credit for having elucidated these important and interesting injuries:

"A man, aged twenty, had been kicked by a horse and on recovering consciousness complained of abdominal pain. The other symptoms were: collapse, frequent vomiting with an occasional streak of blood in the vomit, temperature of 100° F., all subsiding in the course of four or five days. After leaving the hospital paroxysms of epigastric pain with vomiting recurred about weekly, lasting two or three days at a time. After three or four months an unusually severe attack caused the man's readmission. There was some distention of the abdomen and slight elevation of temperature. Recovery ensued, but about a month later a sudden and severe attack was followed by a swelling in the left hypochondrium. An aspirating needle was inserted and twenty-nine ounces of fluid withdrawn. Finally, incision was made and a cavity found containing a further quantity of dark brown fluid. Death occurred from exhaustion a few hours later. On opening of the abdomen signs of recent peritonitis were found. Situated behind the stomach and co-extensive with its posterior surface was an enormous encysted hæmatoma containing red coagula. It appeared as if the hemorrhage might have occurred

FIG. 3.—Cyst of Pancreas Complicated with Discharge of Fluid into the Peritoneum. 1, Stomach; 2, pancreas; 3, cyst of pancreas; 4, lesser cavity of peritoneum; 5, transverse colon; 6, liver; 7, place of rupture in pancreatic cyst.

¹ British Medical Journal, 1892, quoted from Sajous' Annual.

from some ruptured vein in the gastro-splenic omentum, found its way inward, and gradually become encysted between the peritoneal coat of the stomach posteriorly and the peritoneal covering over the pancreas. No special examination of the pancreas for injury was made."

In 1892 I had an opportunity myself to operate in a case which was similar to this case of Lloyd. The operation was performed, however, within a few hours after the injury.

A young colored man had leaped from the platform of a railroad car while the train was in motion. He fell flat on his abdomen against some bridgework. Brought to the John Sealy Hospital in Galveston, he exhibited all the signs of excessive internal hemorrhage and pointing toward the region of the spleen as the seat of his trouble. I expected to find a rupture of it when I made an incision on the outer border of the left rectus muscle. But there was only a slight rent of this organ and not more than a tablespoonful of fresh blood. Toward the stomach, pent up in the omental pouch, an elastic mass could be felt. The patient was then in a dying condition and in order to get him from the table alive, nothing else but closing the external wound was done. He expired an hour or so later. Unfortunately no post-mortem examination was allowed by his relatives: but there seems to be no doubt that a hemorrhage from some vessel within the omental bursa had taken place.

As to the further symptoms of pancreatic rupture there must be mentioned nausea, vomiting, and fainting—which constitute the signs of one form of shock. Whether this is peculiar to traumatism of the pancreas, or whether it is a symptom common to blows on all abdominal organs, is a question that can be answered only hypothetically. Goltz's well-known experiments show that blows against the abdomen cause an accumulation of blood in the abdominal veins while the brain becomes anæmic, and that in this way shock is produced. Still, there seems to exist, outside of this mechanism, some influence of the pancreas of its own on the stomach, perhaps on the whole sympathetic system, either by some reflex action or by alterations in the juices of the body, because, even in cases of old standing and in diseases of entirely different nature, such complaints are common. Contusions of other glandular organs—for instance, of the testicles, as is well known—cause a similar complex of symptoms. Perhaps there is a similar mechanism at work.

Of more value as a sign of pancreatic injury is the excessive and often perverted appetite, setting in shortly afterward. It is frequently mentioned by authors and deserves full attention. I do not venture to give an explanation of it. Urine and fæces rarely offer pathognomonic features. How much Roentgen's photographic method will help in the differential diagnosis will have to be seen.

Prognosis.—It is well to take it for granted that in many a case of so-called internal injury produced by blows or falls upon the abdomen the pancreas has been ruptured, and that the alarming symptoms just after may be due to such an occurrence. But it is evident that usually the rent will be so small that it will readily heal and that the exudate will become absorbed. Consequently the patient will recover in a few days. But, on the other hand, an accumulation will show only in the course of time, whenever it has become large enough to form a detectable tumor. Therefore the prognosis ought to be guarded. We may look for final recovery whenever hemorrhage can be excluded or when, judging from the symptoms, it has stopped. That means when the patient comes well out of the shock, paleness disappears, pulse becomes stronger, etc. As to the necessity of an opera-

tion we should also be careful in our prediction. Judging from the experience in our case in which the leakage had continued several weeks, the smooth and shiny appearance of the lining membrane can be taken for a proof that the otherwise strongly excoriating action of the pancreatic juices is powerless on healthy endothelium or epithelium, here as in other places.

From Senn's studies we know that the portion of the pancreas above the rupture of the main duct will atrophy. But we can easily imagine that a superficial rent which does not go through the whole thickness of the gland will do little harm. Besides, it is mostly the head of the pancreas that will be directly hit by the traumatic force, as it is the thickest and at the same time the most exposed part. Thus the large portion below the rent will remain undisturbed. If, however, the rupture occurred in the tail, then perfect atrophy would set in: but whether this will lead to a fatal termination is a question not yet solved. Experiments on animals are certainly not final, but even they are contradictory. Besides, according to Ziegler, an accessory pancreatic gland is often found which may act when the other is destroyed. As a rule, pancreatic ruptures will by their effect upon the gland itself rarely produce fatal consequences. It will, of course, greatly depend upon the extent and situation of the tear, and upon the time it remains patulous. A small lateral slit may leak even continually; the pancreatic secretion may then be absorbed as quickly as it appears in the omental bursa. But an excessive accumulation, filling the widely disturbed point, can and must have a deleterious effect on all the adjoining organs. The celiac plexus may suffer; the pancreas itself, the liver, the gall bladder, stomach, bowels, spleen, the large lymphatic and blood vessels, especially the portal vein, must be pressed on and thus greatly interfered with. The prognosis, therefore, becomes grave if the extravasate continues to increase. Then only surgical interference will relieve the patient. How long the accumulation may go on uninterrupted is not in my power to state from the literature at my disposal. Perhaps, in the end, the extreme distention of the sack will produce atrophy of the pancreas by pressure, and the leakage will thus be stopped and the peritoneum will be given time for absorption. But it would certainly not be good surgery to wait for such a termination.

Treatment.—Immediately after the accident indications for interference will be too vague to be acted upon. Locating the trouble will be mostly impossible and an exploratory laparotomy will be called for only if the symptoms become steadily graver. According to what was said before, slighter injuries may heal on their own account. But when there are unmistakable symptoms of dangerous hemorrhage which do not quickly abate, the abdomen should be opened as soon as practicable. If then no evidence of bleeding is found in the general peritoneal cavity, the omental bursa ought to be incised with due protection of the intra-abdominal structures against the pancreatic fluid. The question whether or not a large transverse incision in the gastro-colic ligament may interfere with nutrition of the colon can be answered satisfactorily. We know from experience in gastronomy that such is not the case. Next we have to empty the omental pouch of its coagula, and if a continuance of the bleeding be found an effort ought to be made to get at the seat of it. By pulling the stomach upward and the transverse colon downward, and with the use of reflected light, we may expect to see our way. Perhaps compression by packing with gauze will answer.

Now, in cases of older standing, in which the continuance of hemorrhage can be excluded, or in which by tapping a pure or a slightly bloody pancreatic-juice accumulation has been made out, from all experience

at our command, drainage of the sack seems a safe procedure. We will then make a small incision over the dull zone between the stomach and the transverse colon, satisfying ourselves of being below the stomach by searching for the great curvature, which can always be recognized by the wreath-like arrangement of the blood-vessels. Then the omental pouch should be punctured with a hypodermic needle and, after the case has thus been made out, an area of about one square inch of the omentum must be stitched to the parietal peritoneum around the abdominal incision, and opened. After the evacuation of the fluids, a drainage tube is inserted and the wound closed around it. Care has to be taken to protect the surroundings of the fistula by ointments, as the pancreatic fluid is exceedingly excoriating. Most probably the secretion will become less and less, though it may take months before it will stop entirely. The selection of the location for incision, whether in the middle or on the left side, as recently done by Howard Kelly,¹ seems to me of little importance. Still, the former is preferable, because the subsequent adhesion of the omentum to the parietal peritoneum will be so located as not to interfere with any abdominal structure; while in the left side by retraction of the previously widely distended omentum a band may form which would be a constant menace to the bowels.

A very interesting point seems to me the explanation of the *modus operandi* of the drainage effecting a cure of the pancreatic rent. Is it the change of the negative pressure in the airtight sack into a positive one; or is it the influence of the atmospheric air, or perhaps the discontinuance of the pulling asunder of the lips of the fistula by the force of the ever more distending pouch? The question whether here, as in other internal fistulæ, outside drainage is a curative expedient, seems to me worthy of closer investigation; or, perhaps, it is a lack of information on my part that I know no other explanation than that of Lawson Tait in connection with abdominal drainage.

Finally, I would like to say a few words in regard to the tumor felt in our second operation. As stated, we tried to solve the conundrum by leaving it an open question between a distended gall bladder in an unusual place and a partitioned-off portion of the omental pouch filled with pus or pancreatic juice, a kind of a diverticulum. But, I confess, neither interpretation will satisfy anybody. Only quite recently the puzzle obtained a solution, at least in my mind, from a paper by Professor Riedel, of Jena,² and I now believe that which I felt was the head of the pancreas. Riedel reports cases in which the swollen pancreas was found directly under the liver and was taken for the gall bladder. He describes an instance in which the pancreatic head presented a hard, easily movable tumor, rising and falling with respiration, situated directly under the abdominal wall, easily grasped by the hand. He says: "A pitiful smile would have punished him who before the operation would have suggested such a possibility." He further shows how the pancreas may become puffed so as to resemble even malignant enlargement from irritations due to inflammatory conditions in connected organs, as the gall ducts, gall bladder, duodenum, etc., which enlargement will recede with the removal of the cause. In our case there was evidently sufficient cause for irritation and the disappearance of the tumor leaves hardly any other interpretation.

Tight Lacing.—Professor Marchand (*Modern Medicine*) says tight lacing sometimes causes gall stones and that cancer is occasionally due to the same cause.

THE INFLUENCE OF COLD UPON A DISEASED HEART.

By ARNOLD LORAND, M.D.,

KARLSBAD.

At the coroners' inquests held on the bodies of the numerous victims of the cold during the winter of 1894-95 in London, it was shown that the great majority of the deceased were either persons with diseased valves of the heart or aged persons with pathological changes in the musculature of the heart. Apparently persons with a diseased or senile heart have not the same power of resistance against the effects of cold as persons with a normal heart.

The temperature of any part on the surface of the body is mainly dependent upon the amount of oxygenated blood with which it is supplied by the heart. Therefore the greatest sensation of cold will be felt on those parts of the periphery of the body which are situated at a considerable distance from the blood and heat-giving centre, or which first come under the influence of the cold on account of their position. So the toes and fingers, the ears and nose, as also the feet and hands, will be more readily attacked by those pathological processes which are caused by the local irritation of the cold upon the surface of the body. We know that chilblains are most frequently met with in anæmic young girls with feeble circulation, and even strong persons with normal circulation, when exposed for a short time to cold of great severity, will become frostbitten on the toes, which lie far away from the centre of circulation, and the same parts will even become gangrenous in old persons with a very weak circulation. On the other hand, where there is a flow of oxygenated blood there will be a rise of temperature. If there is a flow of blood with an inflammation of the skin or phlegmon in the subcutaneous tissue, we see the affected part red, and that spot will also feel warm. From remote times, besides tumor, rubor, and dolor, "calor" has been accepted as one of the pathognomonic symptoms of inflammation. The bright red color will show us that the blood has not been fully deprived of its oxygen, and there is an increase of temperature in the affected part. The same effect can be produced by a local irritation, which will cause an accumulation of arterial blood. The paralytic extremity of a person with infantile paralysis, however, will have a bluish color and will feel cold. From this we can easily understand that when there is such a pathological change in the cardiac valves the periphery of the body will be but scantily fed with arterial blood, as is the case typically in mitral stenosis or when there is such a defect of the valves that venous stagnation in the periphery will result. This is the case in far-advanced mitral insufficiency, or when there is such a degeneration of the muscular walls of the heart that by the feeble contractions of the same the periphery is badly supplied with the nourishing and warming agent. Persons with such a diseased heart will have a keener sensation of cold and will more readily succumb to exposure to severe cold of short duration, or of a comparatively small degree of frost of prolonged duration.

When the cold is acting upon our body it has a double effect, *i.e.*, the irritation of the periphery of the body and the irritation of the nervous centres consequent upon this. But I think it would be just as right to say it has only one effect, as the action upon the nervous centre is merely the consequence of the irritation exercised by the cold upon the skin. The amount of the irritation of the nervous centre will exactly answer to the amount of the irritation of the skin. As the irritation of the skin by the cold, however, causes by its local effects a mechanical hindrance to

the circulation, I shall treat the two effects from different points of view.

Let us analyze now the local effects of cold when we expose our hand to the same. We have a sensation of cold and the hand will become white and corrugated, as the first effect. This shows that by the irritation of the vaso-constrictors the vessels of the skin have themselves contracted. But next we will see that our hand becomes bright red. This shows that the vessels have been dilated and the blood can more easily pass through the same. It circulates better; therefore the red color. This effect we must attribute to the action of the vaso-dilators.

The bright red color of the skin will, however, soon give way to a bluish coloration. This shows that the circulation has become slower, as there was time for the blood to be deprived of its oxygen. When persons, especially those with feeble circulation, are exposed for a long time to even slight cold, we see their face and hands become the same color. Evidently in consequence of the long duration of the cold there is a slower circulation. I shall refer to this later on.

When now an extremity is still longer exposed to the cold it will appear white, and this white color may even become waxy when the extremity is too long exposed to the effects of a severe frost. We know that persons killed by frost have a very pale color of the skin, even a waxy whiteness. What does this white color of the skin indicate? It shows that there is no supply of arterial blood, as the vessels have been so contracted that even the blood corpuscles cannot pass them. And if the extremity be still longer exposed to the cold after the circulation has ceased in it, it will become gangrenous.

When the skin has for a long time been exposed to the cold the circulation will be hindered, as the vessels will become strongly contracted. We shall see later the consequences of this for persons with a diseased heart.

We know also that cold is able to cause local inflammation of the skin. According to Erasmus Wilson, chilblain is an inflammation of the skin induced by the cold. In its erythematous stage the chilblain is a congested spot, which is first bright red and later becomes livid. The parts affected by frostbite are first bright red and later become livid.

When a person takes a cold bath the first sensation will be one of cold, his skin will be corrugated (*cutis anserina*), but the first white color will be followed by redness of the whole body, and he feels exhilarated and has a feeling of warmth. If he remains still longer in the cold bath the exhilaration is followed by depression. Through the irritation of the skin by the cold a greater amount of blood has been sent to the periphery, and the exhilarated state will show that the brain has been supplied with a strong wave of arterial blood. This state is, however, followed by depression, and the surface of the body is but poorly fed with arterial blood if the stimulating action of the cold lasts for a long time. Winternitz has shown by an interesting experiment that through thermal influence acting upon the skin, there will be an afflux of blood to the periphery. When a man was put naked into an empty tub, the lower part of his body being covered with water (50° F.), the plethysmograph showed that the arm was considerably increased in volume.

Foster¹ mentions that when there is increased general arterial pressure, as for instance that caused by stimulation of a sensory nerve, there is a greater flow of blood to the brain, causing an increase of the volume of the brain.

How are these consequences of thermal irritation of the surface of the body brought about? The existence

of a stronger amount of arterial blood on the periphery of the body presupposes a stronger action of the heart. We know that when the vagus is irritated the contractions of the heart are reduced in number; the diastole, however, is longer, a greater amount of blood accumulates in the heart, and with each pulse a stronger wave is sent to the periphery. But we know also that when the splanchnic is irritated the abdominal vessels contract and there is less blood in the abdomen; but the periphery of the body is better supplied and a stronger wave of blood also is sent to the brain; the pressure in the heart rises. According to the experiments of Stricker, Ostroumoff, and others, this is caused by reflex dilatation of the peripheral vessels.¹

It has been shown through the experiments of Nauman that thermic irritation has an effect upon the splanchnic nerves. When, namely, to the surface of the body of a frog, whose trunk has been left in connection with the leg only by the ischiatic nerve, a weak thermic irritation is applied, the vessels of the mesentery (which as we know stand under the vasomotor regulation of the splanchnics) contract and there is an increased activity of the heart. When a very strong thermic irritation has been used, the vessels of the mesentery become dilated and the action of the heart grows weaker.

When the skin is exposed to the cold we have the sensation of an irritation of the skin through the contact with the cold. In many persons this causes a disagreeable feeling. As Foster, however, says, when the stimulation of the skin exceeds a certain limit of intensity, the sense of temperature is not appreciated apart from the sense of pain. If we cause pain of certain amount to a person, we will see a series of symptoms which will indicate to us a stronger action on the side of the heart caused by a reflex action on account of the irritation of the sensory nerves. If, for example, we remove the tuberculous glands from the neck of a young girl without an anæsthetic, we see the face become red and the surface of the body feels hot. If a boy is punished for some mischief and receives a few blows, the same symptoms are manifested. When a person, however, receives many blows for a longer time his face will become pale, the surface of his body will feel cold, and there may even be cold perspiration on the whole body. When a person receives blows on many parts of the body for a prolonged time, let us say for several hours, he may fall dead. Such a case has been reported by Taylor.² A man had beaten a youth of sixteen most severely for two hours with a rope and a stick. Death followed. At the autopsy no mortal wound was found, but there was internally a large effusion of blood, which, as Taylor remarks, would account for the production of a fatal syncope. The same fatal end we can also see in persons who are burnt or scalded over large surfaces of the body. In such a case also there might be no anatomical lesion which would account for the fatal issue.

When, now, the whole surface of the skin, that large nervous area, is exposed to severe cold of short, or to less severe cold of prolonged, duration, through the sum of the injurious impulses attacking the sensory nerves on the surface of the body such a nervous exhaustion may be brought about that the same fatal issue as in the above case will occur, *i.e.*, such a person will die from shock.

As we have seen before, when there is a slight thermic irritation the nervous centres will be gently irritated, the contractions of the heart will diminish in number, the diastolic period will be longer, the pulse waves will be stronger, and through the irritation of

¹ S. Stricker: "Vorlesungen über allgemeine und experimentelle Pathologie," p. 213.

² Taylor: "Principles and Practice of Medical Jurisprudence," p. 613. Edited by Stevenson.

¹ M. Foster: "Text Book of Physiology," p. 1,136.

the splanchnic nerves the vessels of the abdomen will contract. As Ostroumoff, Stricker, and others have shown, there will be a reflex dilatation of peripheral vessels, and the brain will also receive more arterial blood; when, however, this thermic stimulation passes on to thermic irritation and then to thermic injury, there will be an over-irritation of the nervous centre, the contractions of the heart will increase in number, but the pulse wave will be smaller and the vessels of the abdominal organs will dilate; there will be an accumulation of blood in the abdomen and a contraction of the vessels on the periphery: there will be but a small quantity of blood carried to the heart and later on even that will cease. In consequence, the medulla oblongata will not receive a sufficient amount of blood, and if this injurious over-irritation of the nervous centre persists there will come no blood to the medulla, and death will follow. The death so caused is analogous to that following extensive hemorrhage *z.c.*, it will be a death by syncope, brought about by the same agent, as we have seen in the case related by Taylor.

As I have shown above, persons with a diseased heart have a keener sensation of cold, chiefly on account of their periphery being scantily supplied with oxygenated blood, and accordingly we can easily understand how shock from cold will more readily develop in such persons than in persons with a normal heart. We might even suppose that persons with a considerable defect of the heart and very weak circulation might succumb to the prolonged duration of such a degree of cold, especially with damp atmosphere, which would only have a stimulating effect on robust persons. Several such persons have been found dead in their lodgings, even in their beds, during a period of severe frost. It is certain that such a fatal end can be more easily brought about in persons who, besides suffering from a heart defect, are badly provided with food and in a state of starvation, and especially when the cold is associated with dampness or fog. Mental depression also increases the susceptibility to cold.

Finally, I may mention the unfavorable influence of large doses of alcohol, which, as we know, causes a fall of bodily temperature. When the surface of the body is exposed to the cold, there will arise a venous stagnation, and after this the vessels will so contract through the persistent influence of cold that even the red blood corpuscles will not be able to pass through; so that the circulation on the surface will cease.

It is evident that when there are such disturbances in the circulation of the periphery, the resistance offered by the pressure in the arteries will increase and a great strain will be put upon the heart. This will be the more serious in persons who have a weaker peripheral circulation on account of a heart defect. To overcome the resistance on the periphery the heart must make stronger efforts, as the pressure in the heart should be greater than that in the arteries. The contractions of the heart must become stronger to overcome the peripheral impediment, but the main impulse to the contractions of the heart is given by the presence of a sufficient amount of blood under a sufficient pressure. The contents of the heart should act upon the ganglia and the muscles of the heart, but on account of the disturbance of the peripheral circulation the heart will receive smaller quantities of blood.

The same degree of cold that causes a stagnation of the circulation will also be liable to bring about the symptoms of shock by reflex irritation of the nervous centres. Accordingly, as we have seen above, the blood will accumulate in the abdominal organs and the heart will not receive the necessary amount. The chain of fatal circumstances, however, is not yet complete. There will come another hindrance of the cir-

culation through the disturbance of respiration. As Claude Bernard has shown, when the body is under the influence of low temperatures, the blood will not be supplied with a sufficient amount of oxygen. According to Rosenthal, we know that when the blood that is brought to the medulla oblongata has not a sufficient amount of oxygen, the respiratory centre will be irritated and dyspnea will arise. But there will be another effect. As has been shown by experiments made on animals by Traube, Ludwig, Thiry, Stricker, and others, when the blood passing to the medulla is insufficiently oxygenated, symptoms indicative of irritation of the vagi and of the vasomotor centre are observed, and thus over-irritation of the latter through the process of suffocation brings about the same symptoms as those just described. But the disturbance of respiration has also a bad effect upon the return flow of the venous blood.

Under certain circumstances the hindrance of the return flow of the venous blood through gravity, as when a person has been standing upright for a certain time, may also have a fatal effect. Such might happen when a person with feeble circulation (as in consequence of a diseased heart, for instance) should stand for a certain length of time on the corner of a street exposed to the cold.

And this is the vicious circle of injurious influences acting upon a diseased heart. The greater the cold, the greater will be the sensation of cold, but also the greater will be the mechanical impediments to the circulation at the periphery, and, we may presume, *ceteris paribus*, the more will the blood be in want of oxygen. When the irritation of the sensory nerves causes symptoms of shock, the blood accumulates in the abdomen and there is a reflex contraction of the vessels at the periphery. When the circulation at the periphery is disturbed mechanically, there will be smaller quantities of blood carried to the heart, and through the same cause there will also be a great strain put upon the heart. When through the action of the cold the blood is in need of oxygen, the respiratory centre is irritated, dyspnea arises, and the circulation is again impaired; less venous blood is received from the heart, but at the same time the vagi are irritated and also the splanchnic nerves.

Through over-irritation of the vagi the contractions of the heart are increased in number and the periods of diastole are shorter, as has been shown on dogs in the experiments above referred to. If such animals live longer, as Stricker remarks, in the last stages the periods of diastole will again become longer through the paralysis of the motor centres.¹

Shock, as I pointed out, occurs more readily in a person with a diseased heart; the disturbance of the circulation on the periphery will also be greater; the dyspnea (if not caused already by a scanty supply of blood to the medulla oblongata by reason of the heart disease—mitral stenosis, for instance) will be still greater, as the blood is in need of oxygen through the action of the cold. All these factors act upon the diseased heart, and are caused by the action of cold upon the skin. And as the skin is, as I would say in German, the "Angriffspunkt" (point of attack), I might venture to say such persons will die by the skin.

Dieberg, in the *Vierteljahresschrift für gerichtliche Medizin*, says that in all cases of death from cold in Russia he always found the cavities of the heart full of blood. This might seem to contradict what I have said above, but we must bear in mind that there is a difference in the post-mortem symptoms in cases in which death is caused by the action of very severe cold of short duration and in those in which death

¹ S. Stricker: "Vorlesungen über allgemeine und experimentelle Pathologie," S. 197.

has followed the action of less severe cold for a protracted period. In the first case there is such a powerful over-irritation of the nervous centres by the cold that the heart stops suddenly and there is no possibility of expelling the contents of the heart. In the second case the cavities of the heart are empty just as they are in syncope caused by excessive hemorrhage; no blood comes to the heart and there is no blood there to be sent to the medulla.

We know from experiments on animals that a strong irritation of the vagi may arrest the action of the heart. This has also been observed in men. E. Brücke,¹ in his text-book on physiology, relates such a case. A man in Vienna had complained to his physician that he sometimes had a feeling of great anxiety and at the same time his heart would stop. At the autopsy of the same patient it was found that the vagus on one side was embedded in a large mass of swollen lymphatic glands, so that pressure might easily have been exercised upon the vagus, which arrested the heart.

What are now the therapeutical points to be gathered from the above considerations? We must remove (1) the cause and (2) the consequences.

To satisfy the first indication we must send patients who can afford it to the South. This will be the more advantageous, as they will then be free from bronchitis, to which they are inclined on account of the congested state of the lungs. When this is impracticable we must warn patients with a diseased heart not to expose themselves to cold, to clothe themselves very warmly when they go out, and also to take an abundance of nourishing food.

To fulfil the second indication we must improve the circulation. Therefore we must administer medicaments which stimulate the action of the heart, act as tonics, and prevent the symptoms of shock. Among the most powerful stimulants and tonics for this purpose we might use with advantage strophanthus, arsenic with iron and strychnine (especially when there is fatty degeneration of the heart), caffeine, etc. A natural and very efficacious remedy for our purpose is alcohol, to be given, however, only in small doses. We must recommend the patient to take brandy or whiskey, diluted with double the quantity of hot water, in small quantities, several times a day; and in connection with it we might administer with the best advantage tonic doses of quinine. The stronger kinds of wines, which contain a greater amount of alcohol—as port wine or the stronger Spanish and French wines—have perhaps the advantage over brandy that larger quantities of them can be taken. For those who cannot afford wine, we might recommend small cups of black coffee with a few drops of brandy, or larger cups of tea several times a day. We know from our own experience that when we have been exposed to cold for a certain time by walking or standing in cold air or sitting in a cold room, we have symptoms of depression which are exactly the same as those which precede the symptoms of shock. At such times black coffee in smaller or tea in larger quantities, as also alcohol, removes the symptoms of depression. To a less extent we will see the same effect from the use of a light cigar or a few cigarettes. The same remedies are also efficacious to remove the symptoms of mental depression by causing a greater flow of blood to the brain.

Besides the above remedies, medical movements will have excellent results by bringing about a better peripheral circulation and by reflex action upon the heart. In the treatment of the symptoms of shock we may obtain very good results by applying friction to the whole body in connection with a kneading of the abdomen, which, as I have pointed out in a previous

article¹ on the "Treatment of Fainting," brings a greater amount of blood to the heart and brain. During this operation the patient should lie horizontally or with the head lower than the body.

ARREST OF SMALL-POX IN ITS VESICULAR STAGE.

By ALONZO BRYAN, M.D.,

DETROIT, MICH.

ON Monday, January 14, 1895, at a stated meeting of the Detroit Medical and Library Association I advanced the theory that small-pox can be arrested in its vesicular stage. About twenty persons were present, all or most of whom were members of the society, and they accorded my theory considerable applause and encouragement.

In the paper which I then read I maintained that the eruption of true small-pox only extends to and includes the vesicular stage; and that the vesicles are simply infectionaria through which pus germs and saprophites are intromitted to the structure of the true skin and to the general system. The paper claimed that the germs of suppuration and of putrefaction are lying in wait, embedded in the epidermis, ready to commence their ravages upon the true skin and system at large as soon as their liberation is effected through the instrumentality of the maceration of the epidermal layers by the fluid of the vesicles.

Furthermore, in the same paper, I declared it as my opinion that the aforesaid pathological germs might be forestalled in their pernicious action by means of germicidal fluids applied to the general surface of the body, whereby a complete maceration of the epidermis could be effected. To accomplish this object I proposed baths of long duration in antiseptic fluids. In a word, I suggested the cautious and gradual evolution of a system of disinfection to be applied to the entire epidermal covering. When the epidermis was disinfected it was to be kept that way by means of suitable antiseptic dressings applied to the cutaneous surface until the complete desiccation of the vesicles.

By means of such a course I proposed to arrest the small-pox in its vesicular stage, and completely prevent suppuration of the skin and suppurative fever with its various dangerous complications. The above statement expresses only the cardinal principles of the subject as discussed by the paper. Up to the present date, June 4, 1896, the paper has never been published.

A few days after having read my paper before the Detroit Medical and Library Association, I assumed charge on January 22d of the Small-pox Hospital at Detroit. I supposed that I should have abundant opportunity to test my theory, but in this expectation I was rather disappointed than otherwise. My appointment was looked upon as a political arrangement, my theory was freely advertised and adversely criticised by the newspapers, the general public was enraged, and the poor, unfortunate patients at first looked upon me with dismay rather than with confidence. Suspicion and distrust were depicted upon all of their countenances. I found the hospital the last place in the world to exploit a theory. Furthermore, I was deprived of my office on March 9th, by reason of a previous act of the State legislature.

According to my view it was necessary to commence the treatment for the arrest of the disease either during the primary fever or at least in the incipency of the papular stage of the eruption. After the slightest degree of pustulation had supervened it would be too late. Nearly all the patients who arrived at the hos-

¹ E. Brücke: "Vorlesungen über Physiologie," S. 113, ii. Band.

¹ Wiener med. Presse, Nos. 70, 71, 1895.

pital arrived after the vesicles were beginning to become purulent.

However, one case was on the ground sufficiently early. It was the case of a woman named Mrs. Lena Press, who came as a nurse to attend her sister who entered the hospital fully broken out with the small-pox. This woman, while attending her sister as a nurse, in due time came down with discrete small-pox. In this case the circumstances were such that I only ventured to apply my treatment with the view to the prevention of pustulation locally. I made my applications to the hands and forearms, which showed a very free and perceptible papular eruption. The papules all developed into vesicles, but only a very small number became purulent, dotted here and there. The vesicles dried up and assumed the appearance of flat, dark brown, desiccated scales, closely adherent to the skin. In due time they were exfoliated, leaving no scars or pits behind.

In this case on every other part of the skin than those that were treated, the vesicles developed into the complete and typical pustules of variola; the demarcation at the elbows sharply showing the difference between the arrested eruption and that which was allowed to proceed.

And this was the manner in which I proceeded to arrest the development of the eruption. I first scrubbed the skin of the forearms and hands with a strongly alkaline soap and water in order to remove the oil naturally existing in the epidermis. Then I washed the skin with alcohol to kill germs and also to remove oil. Next the skin was washed with a 1 to 500 solution of mercuric bichloride. Then it was washed with a solution of hydrogen peroxide. Each of these washings was of ten or fifteen minutes' duration. Finally the parts were well wrapped in a thick envelope of borated cotton.

The above washings were repeated daily for three days, and the borated cotton was applied for a day or two longer.

It should be noted that I would not recommend a universal bath of a solution of the bichloride of mercury on account of its possibly dangerous systemic effect.

I did not give this woman who was the subject of experiment universal baths of antiseptic solutions, because I did not believe she could be prevailed upon to consent to their use, for she evidently shared in the mistrust which reigned throughout the hospital.

Indeed, according to my theory, I should have expected a very imperfect or negative result from the merely local application of antiseptics. Especially would I have looked for failure in a case of confluent small-pox; and for this reason, that after the supuration of a large number of untreated vesicles enough pus-germs would be found absorbed into the general circulation to effect a supuration of the superficially sterilized vesicles, upon the well-known principle that bacteria floating inertly at large in the system may localize themselves by attacking a weakened and non-resisting part. Nothing is more clearly demonstrated in pathology than that pus-germs existing in a state of general circulation often concentrate themselves upon a focus of least resistance and there display their specific energy. So we might reasonably expect a vesicle of variola to be such a focus, and though it might be protected from external infection it could be successfully assailed from within.

Therefore, in a case of discrete small-pox (such as the subject of my experiment was), the damage from the intromission and subsequent localization of bacteria might be trifling, yet in a case of confluent small-pox the phenomena of what might be termed intra-infection would doubtless be very grave.

And from this very cause we might infer how essen-

tial it would be to immerse the patient for hours at a stretch in a suitable germicidal fluid, and at a period, if possible, before the papules had begun to show any accumulation of serum at their apices.

The main principle is to macerate the whole epidermis thoroughly with some suitable antiseptic fluid; and to do it before or at the very incipency of the eruption.

REMARKS ON SOME SKIN DISEASES OCCURRING IN CONNECTION WITH GASTRO-INTESTINAL DISTURBANCES.¹

By FRED. J. LEVISEUR, M.D.,

DERMATOLOGIST TO THE RANDALL'S ISLAND HOSPITALS AND GERMAN POLYCLINIC

THERE are a number of skin diseases which occur in connection with disturbance of the stomach and the intestine.

This fact is well supported by clinical evidence, but, viewed from the more elevated standpoint of theoretical science, it must be admitted that the true nature of this connection is far from being clearly understood. I shall not enter into a discussion of this difficult question, nor shall I attempt to solve any one of the many problems with which such a discussion must confront us at every step; but I simply want to put together, bring more prominently into view, and comment on a few common and several rare skin affections which appear in patients suffering from intestinal disturbances, a condition which renders these cases equally interesting to the clinician and to the dermatologist. In doing this it was unavoidable to disregard more or less that somewhat artificial but highly important dividing line which separates symptomatic from idiopathic cutaneous eruptions.

One of the most common forms of eczema, called eczema infantile, characterized by symmetrical red patches covered entirely or in part with yellowish crusts (*crusta lactea*), is in a vast majority of cases due to derangement of digestion. As a rule, we have to deal with babies who are unusually fat. In fact, they are overfed; their little stomachs are constantly full and distended. Frequent vomiting, nature's safety measure for infantile gluttony, is not sufficient to relieve the overtaxed organ, which reflects its abnormal condition through the vasomotor nerves by producing a local hyperæmia of the face. The highly congested parts begin to itch, the child scratches its face or rubs it against objects within easy reach. Moisture from the mouth macerates and again irritates the affected parts. Occasional constipation alternating with slight diarrhœa is almost always present. Sleep is fitful and much disturbed.

In another class of cases of this disease, comprising children under six months of age, when the salivary glands are still functionally inactive and consequently unable to dissolve and absorb starch, the gastro-intestinal disturbance is caused by giving the young infant starchy food.

It has been ascertained beyond a doubt that in a number of cases the eczema disappears as soon as the diet is regulated or a radical change in feeding is made; that on the other hand local treatment alone is often insufficient to effect a permanent cure. The baby should be nursed not oftener than four times during the day and three times during the night, and at regular intervals. If cow's milk or artificial food is given its composition should be investigated; its action should be watched and possible errors corrected accordingly. Among medicinal remedies calomel in the dose of one-tenth to one-fifth of a grain three times a day can be recommended. Dilute muriatic acid and

¹ Read before the Manhattan Medical and Surgical Society.

very small doses of creosote may also be tried. Local applications should by no means be neglected. Their quieting effect alone makes a change of the alimentary regimen very much easier. Some cover the face with a soothing salve or paste spread on lint, which is bandaged down in the manner of a mask with apertures for the nose, mouth, and eyes; others attain the same results by using the calamine-and-zinc solution, or some mild paste or salve without bandaging.

All writers agree that a large percentage of cases of acne rosacea is caused by indigestion. We often find this disfiguring affection in alcoholics, but also in men and women who drink nothing stronger than tea. These patients have *fœtor ex ore*, especially in the morning, sour eructations, constipation, and perhaps a distressing feeling of fulness after meals; in short, all the symptoms of a mild fermentative gastritis. I have observed that in most cases the teeth are so decayed or defective and the mucous lining of the buccal cavity is so swollen and congested that the patients do not masticate their food properly. I am unable to say whether the indigestion is the cause of this pathological condition of the mouth or *vice versa*, or whether there exist a direct connection between the dental and the skin affection by way of reflex action on the dental branches of the fifth and the vasomotor nerves. It is possible that these different etiological factors co-operate in producing acne rosacea, which essentially is an angio-neurotic affection. Of twenty-four cases observed among the workhouse men and women at Randall's Island (mostly inebriates) fifteen had extensive dental defects, so that mastication was positively interfered with; in five cases the teeth were very much decayed, but the patients were able to masticate their food. In only four cases were the teeth not worse than would be expected. The age of the patients ranged from thirty to forty-five years. The most pronounced case of acne rosacea seen by me of late concerned a gentleman who kept a restaurant which was said to have quite a local fame for good Rhine wine. This wine was, however, made by the patient himself, as he told me in confidence, from grapes by a primitive process. I found that this wine was very sour, probably on account of imperfect acetic-acid fermentation. The patient, who was in the habit of drinking a bottle or two of it every day, had a very pronounced fermentative gastritis. Many of his teeth were missing, broken off, or decayed, and the gums were swollen and had a bluish appearance.

It must be remembered that in women near the climacteric neuroses of the stomach occur quite frequently, and it is therefore often difficult to decide whether some cases of acne rosacea in women with uterine affections are due directly or indirectly to reflex from the genital sphere.

In severe cases lavage is indicated and has sometimes a surprisingly good effect on the skin eruption. It must not, however, be expected that the mechanical removal of the fermenting masses stops the fermentation: the latter will promptly start again with the very next food supply. Careful dieting is almost always necessary: the amount of carbohydrates should be limited: alcohol, tea, pastry, the coarser vegetables, and milk should be forbidden. Bismuth, carbonate of sodium, creosote, carbolic acid, thymol, and ichthyol may be employed. I have had good results from the use of the fluid extract of ergot. According to Wertheimer and Magnin, ergot produces very active movements in the coats of the stomach, and Wright found very active intestinal peristalsis at the post-mortem examination of poisoned animals. Besides having this action on the intestines, therapeutic doses of ergot increase blood pressure by stimulating the vasomotor centre in the medulla. The condition of the teeth and mouth requires close attention. Cavities

ought to be filled by the dentist, roots removed, and the use of artificial teeth recommended if necessary. Local treatment is of course of great importance, especially scarification of the enlarged blood-vessels.

It would carry me too far if I were to consider the various drug eruptions which appear in connection with gastro-intestinal disturbances, as for instance erythema after the use of quinine, antipyrin, turpentine, balsam of copaiba, sandalwood oil, arsenic, etc.

Urticaria appears in certain individuals after eating strawberries, gooseberries, raspberries, lobster, oysters, fish, oatmeal, sausage, etc. That we ascribe the disease to an idiosyncrasy, a term devoid of scientific meaning, is an open confession of our ignorance of the true nature of the poisonous agent. After excluding all cases of purely nervous origin (for instance, those caused by anger, shame, excitement, etc.), a distinction can be made between cases of gastric and intestinal origin. In the former class of cases the rash appears in a remarkably short time after the ingestion of the special article of food, very much like the nervous effect of some poisonous drugs. If vomiting occurs, it may cut short the attack and be followed by immediate relief. One attack seems to confirm and intensify the susceptibility to subsequent attacks. I do not believe that neuropathic, hysterical individuals are most liable to have attacks of urticaria. I have often observed that otherwise healthy persons become neurasthenic after repeated attacks of urticaria.

The absence of all gastro-intestinal disturbances in a case of urticaria is a negative symptom, sometimes of great diagnostical value. It may mean the bursting of an hydatid cyst of an internal organ.

Urticaria of intestinal origin appears more slowly and is of a more chronic nature. In some cases there is dilatation of the stomach and when the patient becomes somewhat constipated the attacks appear half an hour till an hour after meals and last for several hours. This is a very obstinate form of the disease, and many remedies may be tried before a cure is effected. W. Osler has observed eleven cases of exudative erythema appearing with gastro-intestinal crises. Subsequent attacks sometimes appeared without the skin lesions. There may be simply colic of all grades and intensity, from a transient, readily borne belly-ache to an attack of such agony and duration that repeated hypodermics of morphine have to be given. Vomiting and diarrhoea are frequent but not necessary accompaniments of the attack. The disease bears no relation whatever to food and may come on abruptly in a person in excellent health. Of sixty cases mentioned in the literature (Osler's eleven included) thirteen died, giving a mortality of 21.3 per cent. There is no intestinal hemorrhage, as in the infantile purpura of Henoch. The affection resembles in some respects the giant urticaria, or angioneurotic œdema of Quincke, which is characterized by nausea and vomiting appearing in connection with an œdema of the eyelids, lips, or cheeks, sometimes the backs of the hands and the legs. If the œdema occurs in the larynx the disease may prove fatal. According to Natas there may be a remarkable periodicity in the outbreak and there seems to be a marked hereditary disposition in the disease.

Pellagra, an endemic disease, so very prevalent in Northern Italy and occasionally also met with in Southern France, develops according to Lambrose under the influence of a diet of diseased maize. The disease begins with malaise, indigestion, and diarrhoea. Then an eruption appears on the exposed parts of the body, the exciting cause being ascribed to the action of the sun's rays. It is an erythema accompanied by pigmentation, desquamation, and pruritus. Later on the skin assumes a dark olive-brown hue and petechiæ appear on the belly and chest. An

endemic disease closely resembling pellagra, called acrodynia or erythema endemicum, was observed in Paris about 1830. Mention is made here of these affections because it has been suggested that possibly other grains, such as oats, may undergo similar changes and produce similar effects.

Indigestion and constipation are often found to be associated with pruritus universalis occurring in middle-aged persons. It is impossible to say whether the gastro-intestinal disturbance has any etiological significance or is simply a concomitant symptom. If a conclusion *ex juvantibus* be allowed, I can say that a strict milk diet carried out thoroughly in a number of severe cases seemed to do no good.

That the secretions which the food meets with in the intestinal canal are antiseptic in their action may be anticipated, according to Kirke, not only from the proneness to decomposition of organic matters, such as those used as food, especially under the influence of warmth and moisture, but also from the well-known fact that decomposing flesh (high game) may be eaten with impunity. The absorption of products formed in the intestine by the decomposition of the albumin under the influence of bacteria, a process called auto-intoxication, has recently been claimed by many authors to be the cause of attacks of erythema, urticaria, herpes, and pemphigus. An increased quantity of indican (dioxyl sulphate of potassium) is claimed by Singer to be a sign of idiopathic urticaria caused by auto-intoxication. The subject of indicanuria in relation to skin diseases certainly needs more extensive investigation. Clinical experience confirms the opinion that exacerbations of many skin diseases, eczema, furunculosis, acne, psoriasis, may be traced to absorption of poisonous products in the intestine.

640 MALISON AVENUE.

A NEW FLUORESCENT SUBSTANCE.

BY LÉON BERTRAND, M.D.,

ANTWERP,

SURGEON SS. SOUTHWARK, RED STAR LINE.

I BEG to introduce to notice a new fluorescent chemical discovered by Dr. Edm. Van Melckebeke, of Antwerp, which is called double fluoride of uranyl and ammonium. I had the honor two weeks ago, at a meeting of the Société Médico-Chirurgicale of Antwerp, of demonstrating Edison's fluoroscope, which was very highly appreciated, indeed; but I have to confess impartially that it is equalled in every respect by Dr. Van Melckebeke's discovery, which I had the pleasure to experiment with myself. Moreover, this last has the advantage of being very cheap.

The following is the manner in which Dr. Van Melckebeke discovered his new chemical: First, recalling the fluorescent properties of the nitrate of uranium, he made a solution of that substance and coated a piece of cardboard with it; but no fluorescence was obtained under the "X" rays. He then modified the method of impregnating the cardboard, and, instead of coating it with the solution, he fixed the nitrate of uranium on the cardboard through the medium of a gummy solution. The screen then became fluorescent under the "X" rays.

Dr. Van Melckebeke explains the failure of the first method to produce fluorescence by the fact that the solution impregnated the fibre of the cardboard, and after evaporation of the water the salt remained either in an amorphous state or in a state of confused crystallization. Fluorescence, like rotatory polarization, seems to require a state of perfect crystallization.

Among the chemicals which precipitate in a state of perfect crystallization are the double fluorides.

Wurtz's Dictionary (vol. iii., p. 561) mentions a double fluoride of uranyl and ammonium with the formula: $\text{U}_2\text{O}_2\text{F}_2, \text{NH}_4\text{F}$.

If one drop of nitrate of uranium and a particle of fluoride of ammonium are brought together, they will produce regular octahedrons. But if larger quantities are used, five hundred and four parts of nitrate of uranium and one hundred and eleven parts of fluoride of ammonium, according to the formula of Wurtz and the equation:

no crystals are produced.

Dr. Van Melckebeke increased gradually the quantity of fluoride of ammonium in the proportion of about one part of fluoride of ammonium to two parts of nitrate of uranium. He obtained a crystalline deposit, which, examined under the microscope, presented all the characteristics required. After precipitation, the liquid had lost its color entirely.

In order to obtain this result, the proportions to be used seem to correspond approximately to the formula: $\text{Ur}_2\text{O}_2\text{F}_2, 4 \text{NH}_4\text{F}$, according to the equation:

The deposit is put in a filter, is washed with cold water, and dried. It then appears as microscopic octahedral crystals, yellowish-green by reflection, and colorless in thin coats by transmission; it becomes fluorescent while exposed to the violet rays. These crystals are not very soluble in cold water, but are more soluble in boiling water; hence they may be deposited on the surface of objects by simple cooling of a hot saturated solution.

As far as we know, the chemical is a new one. It is certainly different from the one mentioned by Wurtz, as much by its composition as by its crystallographical properties and by its smaller degree of solubility in water. It has some analogy to the double fluoride of uranyl and potassium, $\text{Ur}_2\text{O}_2\text{F}_2, 4 \text{KFl}$, and to the double fluoride of uranyl and sodium, $\text{Ur}_2\text{O}_2\text{F}_2, 4 \text{NaFl}$ (see Wurtz's Dictionary Supplement, vol. ii., p. 1,628).

Oxyfluoride of uranium and ammonium can be spread on pieces of cardboard through the medium of different excipients, such as a solution of gelatin, oily varnishes, etc. This is the best way to proceed: On the bottom of a basin put a sheet of strong blotting paper and cover it with a boiling saturated solution of the oxyfluoride; let it cool, and when the paper is covered with a crystalline coating decant the liquid. Repeat the operation two or three times. In order to give some solidity to the deposit, cover it with a coat of gelatin. The fluorescent power of the chemical prepared in this way seems to vary according to the thickness of the coat of gelatin.

Dr. Henri Van Heurck, of Antwerp, has a good method of photographing the image thrown on these screens. He puts the screen in close contact with the film, and obtains a very good picture in a few moments.

Dr. Van Melckebeke's discovery dates from the beginning of March. The net cost of the double fluoride of uranyl and ammonium is, in Europe, twenty-seven cents an ounce.

Scurvy.—Dr. Cheney says that a "black eye" coming on in an infant without traumatism, and perhaps repeated several times, can rarely be due to anything else but scurvy.—*Medical News*, February 29, 1896.

Progress of Medical Science.

The Presence in the Normal Thyroid Gland of a Substance Containing a Relatively Large Quantity of Iodine.—The demonstration by the distinguished Freiburg chemist Baumann, says the *Medical News*, of the presence of an organic iodine compound in the normal thyroid gland must be regarded as one of the most important of the recent contributions in the field of chemistry. But, quite apart from the interest which belongs to it from a purely chemical standpoint, a much wider significance attaches to the discovery from its therapeutic aspects; for we are now at least promised a solid basis from which may be deduced an explanation of many well-known clinical facts which have been developed not only from the treatment of disease of the thyroid gland with thyroid extract, but from organotherapy in general. Almost simultaneously with the earlier reports dealing with the benefits to be derived in certain diseases from the administration of the thyroid extract, there developed in chemical circles an unprecedented activity in investigating the constituents of the thyroid gland; and the unabated interest which has since prevailed is evidenced by the large number of articles dealing with the subject that have appeared up to the present time. None of these, however, offers a satisfactory explanation of the beneficial influence which has undoubtedly followed this form of medication. The incomplete publications of Notkin, in which it was asserted that two substances—a protein and a ferment—were responsible for the virtues of the gland, have been looked upon, curiously enough, with favor by the French, although physiological chemists in Germany and America have not been inclined to consider them seriously. The crystalline nitrogenous derivative described by S. Fraenkel, although of chemical interest, is insufficient to supply a solution of the problem in question. The idea that the element iodine might stand in some very definite relation to the metabolism of the thyroid gland is by no means new. Even so early as 1850 Chatin, who believed that iodine was present in the air, in water, in all plants, in fermented drinks, in milk, in eggs, and in the soil, suggested that its presence was essential to the welfare of the organism, and that cretinism and goitre occurred only in those regions in which iodine was entirely absent from the drinking-water. Others who studied the constitution of the air and of water denied, however, the presence of iodine in them, and Chatin's theory was at first discredited and afterward forgotten. Kocher, the distinguished surgeon at Zurich, only a short time ago, relying upon the fact that the efficacy of iodine in the treatment of diseases of the thyroid gland compared favorably with that of the thyroid extract, suggested that the normal thyroid gland be examined thoroughly in order to see if iodine existed in it. Tschirsch incinerated the gland, but failed to find iodine, and chemists, relying upon his results, naturally took it for granted that this element was absent. This negative result was perhaps not surprising, considering the small amount of iodine present in the crude gland, though Baumann has since detected it in the ash from one gram of the dried gland. Roos, in a report of an investigation preceding Baumann's publication, in which he showed that the thyroid gland bore a distinct relation to the phosphorus metabolism of the body, mentioned some experiments which may really be looked upon as the forerunners of Baumann's brilliant discovery. It had for some time been known that digestion, moderate heat, and certain antiseptics did not destroy the active substances of the thyroid gland, and Roos proved, in addition, that prolonged boiling in five to ten per cent. solutions of the min-

eral acids apparently did them no injury. It was his opinion that a portion of the active substance, though not all, was soluble in water.

Deciduoma Malignum.—Since 1876 there have been recorded some sixteen cases of a distinct variety of malignant disease of the uterus having histological and clinical characteristics peculiar to itself and sufficiently interesting to deserve more attention than has been bestowed on it. Dr. G. W. Beach has given us a very full account of the disease, besides quoting a case that was under his care. The disease was given the name deciduoma malignum by Gottschalk in 1893, and it is referred to by that name by French authors. The interesting points which pertain to the disease are its undeniable relations to pregnancy and its peculiar pathological anatomy. In the histological preparations made of all the cases up to date a constant element has been found—an immense cell, corresponding to the giant cells of the decidua. These cells are polymorphous, possessing one large nucleus, rarely more than two, and have a homogeneous granular protoplasm. These cells invade the tissues and are found mixed up with other elements in the interstices of connective tissue and inside the muscular bundles. The development of the disease is very rapid, the neoplasm invading the blood-vessels and giving rise to free hemorrhages and attacking the whole uterine wall. Metastases are very common, the lungs and pleura being most often affected. In nine out of the sixteen cases the patients were under thirty. The growth usually appears shortly after childbirth or abortion, but in three cases hydatiform moles marked the commencement of the disease. The majority of authors admit that the neoplasm develops from the debris of the decidua, but at present it is impossible to say why retention of the decidua in one case gives rise to hemorrhages simply and in another to deciduoma malignum. The first sign of the disease is metrorrhagia after a confinement. The hemorrhage is at first intermittent and scanty, but later on increases and becomes incessant, and curetting has no effect in checking it. The patient soon becomes cachectic, and toward the close the discharge becomes putrid and is usually accompanied by fever. Death takes place generally by exhaustion. The disease is very rapid, and general invasion by metastases is certain. On examination the uterus is always found increased in size, the os being permeable or not according as the disease has progressed. The uterine cavity will be found to contain soft pulpy masses resembling placental tissue mixed with blood clots, and in places the uterine wall is softened and the finger sinks easily into the muscle. The diagnosis in the early stages is difficult. If there is intermittent hemorrhage after confinement the proper course is to curette. If the first curetting does not check the hemorrhage, a second must be performed and microscopical examination made of any debris removed. If the uterus is found enlarged and curetting shows softening of the uterine wall in patches, and the characteristic giant cells have been found by the pathologist, the only course is to remove the uterus and appendages as soon as possible. Vaginal hysterectomy has been performed in five instances with recovery in two only, but time enough has not elapsed to show us more than the immediate results, which, however, are good. As the evolution of the disease is so rapid everything hangs on an early diagnosis.—*Indian Medical Gazette.*

Hip Amputations.—Before applying the tube (in Wyeth's technique) the tendons of the hamstring muscles should be cut, in order to equalize the subsequent retraction of the muscles when the circular cut is made.—DAWBARN.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, July 18, 1896.

THE CIRRHOSES OF THE LIVER.

THE history of our knowledge of the cirrhoses of the liver is closely identified with French medicine. It speaks well for the breadth and liberality of the German scientist that in an elaborate discussion on this subject by Professor Senator, before the Hufeland Medical Society, he gives full credit to his French medical brethren.¹

Laennec was the first to separate the cirrhoses from other diseases of the liver, which he did in his celebrated treatise on "Auscultation," seventy-eight years ago. The description which Laennec gave of atrophic cirrhosis remains good to-day, and his name is still associated with one form of this malady. Later authors soon showed that there were other forms, however, associated with hypertrophy of the liver and with jaundice, and having a different cause and clinical history. Many attempts to describe and differentiate the types were made, but it was not until 1876 that Charcot and Gombault gave a classification which to some extent still holds. According to these authors, there is the common cirrhosis of Laennec, with granulations and an atrophy, and due to a proliferation of connective tissue, starting from the portal vein and its branches. Then there is a cirrhosis associated with hypertrophy and jaundice, which starts essentially from the system of biliary ducts, and which is due to obstructions and inflammations in these organs. A third form of hypertrophied liver was noted, as occurring in persons suffering from hereditary syphilis. The distinction between the first two types of cirrhosis—that of portal origin and that of biliary origin—is still, according to Senator, to be maintained, and has been supported by the further and more elaborate researches of Ackermann and other pathologists. It has, however, been found that the precise course of these two types, as described by Charcot and Gombault, is not always observed and that mixed forms undoubtedly occur. In order to meet these clinical distinctions, Senator describes two varieties of the atrophic or granular form. One of them he calls portal cirrhosis with hypertrophy of the liver, the other cirrhosis with icterus. It had been noticed that cases of biliary cirrhosis were followed eventually by an atrophy; hence, Senator establishes a special class of this form of disorder, which he calls "biliary cirrhosis with secondary atrophy," and a variety of this he calls

"biliary cirrhosis with hypertrophy of the spleen." The third and final type is called a "hypertrophic cirrhosis with icterus."

The atrophic cirrhosis of Laennec is characterized by an atrophy of the liver and enlargement of the spleen, absence of icterus, and absence of bilirubin in the urine; later by ascites and dilatation of the veins of the abdominal wall and of the gastro-intestinal tract. This is undoubtedly a common type of atrophy, and is associated usually with excessive indulgence in alcoholic drinks. While some authors consider that in this disease the primary trouble is a degeneration and wasting of the liver cell, with secondary proliferation of connective tissue, it is generally taught that connective tissue, starting from the portal system, begins to grow first and that the cell atrophy follows it. The biliary cirrhosis with atrophy in its typical forms is due to obstruction of the biliary passages by the catarrhal products or by calculi. Here the leading symptoms are decoloration of fecal matters, at first enlargement of the liver, followed by atrophy, without swelling of the spleen and without ascites. The urine contains bilirubin in abundance.

In the third form, that known as cirrhosis of Hanot or the hypertrophic cirrhosis with icterus, the liver is enlarged. The discoloration of fecal matters is little marked and variable. The urine, which is rather abundant, contains generally some bilirubin. The spleen is enlarged and there is here also no ascites nor portal stasis.

This last type of the disease is, according to Senator, very rare, and he admits to have seen only about a dozen cases. Men are more often affected than women, and the essential cause seems to be a catarrhal condition of the bile ducts. The distinctive features are the large liver and the hypertrophied spleen, the enlargement of the liver occurring quite early. This form of cirrhosis is more benign than the portal type and runs a variable course, during which the patient gets now better, now worse. It lasts sometimes ten or a dozen years. A cure is not impossible in these cases and death, when it does result, is due to marasmus and profuse hemorrhage, or, perhaps, to a peritonitis.

As regards prognosis and therapeutics, Senator has little to add to what is already known. The prognosis is bad in all the forms, except, perhaps, in that due to the presence of calculi or other movable obstructions to the biliary duct. In general, the prognosis is bad in accordance with the smallness of the size of the liver, and cases of hypertrophied liver are more favorable than those in which it is of normal volume.

The portal cirrhosis of Laennec, though incurable, can be very much ameliorated by treatment. Alcoholic drinks must be forbidden, and a non-irritating diet, composed largely of milk, must be prescribed. Milk and iodide of potassium, though they seem to be borne by Frenchmen and Italians, agree less with the German constitution; at least, Senator states that, according to his experience, few Germans can habituate themselves to a milk diet for more than a few weeks. It

¹ Archives générales de Médecine.

is necessary in their cases to add something else. Senator is a little skeptical as to the value of iodide of potassium in cases in which there has been no syphilis. He considers it important to puncture the abdomen and relieve the ascites as early as possible, and he finds that the use of calomel and digitalis is helpful. In the biliary types of cirrhosis he uses injections containing a litre of oil and a little soap and water, or solutions of salicylate of sodium, 1 to 1,000, all combined with careful massage of the liver, and from time to time laxatives, especially those known as cholagogues. Prolonged baths, with massage during the bath, and the cures that one gets at such places as Carlsbad, exercise a favorable influence upon the excretion of the bile.

AGAIN THE DISPENSARY ABUSE.

THE dispensary abuse is being recognized and the evils of which it is capable appreciated by the lay public, and this fact is a promise that the near future will bring a remedy. The subject received intelligent consideration at a recent meeting of the municipal section of the Civic Club of Philadelphia—an association constituted solely of women—in a paper read by one of the members, Mrs. Francis Howard Williams. The facts upon which the paper was based were obtained through personal investigation conducted through the medium of a series of questions pertinent to the knowledge desired. After dwelling upon the origin, the usefulness, and the necessity of dispensaries in large communities, the abuses of the system were graphically described. The speaker went on to say that:

"In our desire to make relief easy for the suffering poor, we have weakened their natural powers to help themselves; we have diminished their self-respect and sense of independence; we have made them less helpful as men and women, and more helpless as members in a community in which to live is already difficult, and the way open only to those who bring to the contest a wholesome consciousness of their own worth, with a hearty disposition to work. Not only do the needy and deserving resort to the dispensary. Many go there who would be ashamed to receive a benefit of another nature. There are hundreds who do not scruple to accept a bottle of medicine who would scorn the gift of a loaf of bread; many who use a doctor's time and accept his advice who would refuse a pair of shoes from their shoemaker, although, perhaps, the latter is twice as able to give of the fruit of his labor. It is not only the poor who are willing to depend upon the dispensary; there are some cases among the well-to-do.

"I have been informed that the members of the medical profession, in their anxiety to secure clinical service, are responsible largely for this evil, and that dispensaries are necessary feeders to hospitals; nevertheless, it is evident that if they benefit the medical practitioner at first, he loses in the long run."

Several illustrative instances were cited, showing that an unrestricted establishment of dispensaries is

hurtful to the healthful self-respect of the members of a community, while at the same time depriving the physician of the proper rewards of his labor. The remedy proposed is as follows:

"Cut down the power of dispensaries; restrict their establishment; oblige them to have telephone communication with the charity organizations; establish beneficial associations, in which the physicians are paid salaries, and in which they can afford to treat patients at moderate fees; refuse dispensary aid to persons who are able to pay, and refer them to the beneficial associations for treatment."

DEATH SCENES IN FICTION.

WE do not see on what ground, either of art or science, of public good or private morals, the publishing of medical descriptions of death in popular novels can be justified. We do not mean to say that the novelist should not allow his patients to die if circumstances compel it, or that he should not describe the way they die in as pathetic, dramatic, or tragic a manner as he chooses. But to introduce into the pages of novels technical descriptions of deaths from diphtheria, opium poisoning, tuberculosis, or other malady, is offensive to good taste and is a misuse of the art of fiction. If people want to know exactly how a person dies who has a cancer of the uterus, there are excellent technical descriptions in a large number of standard works; in fact, the literature of medicine is burdened with such descriptions, some of them joining literary skill with technical knowledge.

We are led to these remarks by a perusal of the death-bed scene in a case of diphtheria as described by the at-one-time novelist "Ouida." This lady is, happily, one of the passed among fiction writers, but she seems to be trying to make up for her decaying powers by silly sensationalism. This is the manner in which she describes death from diphtheria: "The poisonous growth filled every chink of the air passages, as though they were tubes mortared up and closed hermetically. His face grew purple and tumid. His eyes started from their sockets. He had no sense left, except the mere instinctive mechanical effort to gasp for the air he would never breathe again. Blood foamed in froth over his lips, which were curled over the white teeth and were cracked and blue. His eyes, starting from their orbit, had no sight. Suddenly the convulsions ceased." This, according to "Ouida," with a few additional trappings, such as nuns kneeling around on the floor, and shadowy lights thrown through the room, etc., constitutes a supposed realistic description of a death-bed scene from diphtheria. It is, perhaps, truer than the death-bed scene from opium poisoning, as described by Marion Crawford, where the patient sinks away with his pupils widely dilated. But, after all, it is not a true picture of the way patients die from this disease. It is partly technical, partly imaginary, and altogether exaggerated, a mongrel affair, such as all medical descriptions of maladies and deaths by novelists must necessarily be.

News of the Week.

Prof. H. Leloir, of Lille, France, died recently at the age of forty-two years. He had been professor of dermatology in the University of Lille since 1886. He was best known for his original work on the subject of neuroses of the skin, but had written many valuable essays on leprosy, lupus, and other dermatological subjects. In collaboration with Vidal he wrote a treatise on skin diseases which is recognized as one of the best in any language. His last work was the preparation of the article on "Dermatoneuroses" in the "Twentieth Century Practice." While he was engaged on the final section of this article last winter, he was the victim of a railway accident, receiving very severe injuries from which he never entirely recovered, and which probably contributed to the fatal termination of his last illness.

The Cholera in Egypt continues with about three hundred and fifty deaths daily. The disease has now made its appearance among the British troops at Wady Halfa and Cairo as well as among the native soldiers. The cable reports that the health authorities of Dantzic made an official certification of a case of Asiatic cholera in that city on July 7th. None has since been reported, so it is probable that that was an imported case from Galicia or the provinces of southern Russia, where the disease is believed still to linger. It is denied that it exists any longer in St. Petersburg or Moscow.

Yellow Fever and Small-Pox are still prevalent in Cuba, the latter being even more deadly than the former. The victims of yellow fever are chiefly the foreign soldiers stationed in the coast towns, but the small-pox attacks natives and Spaniards alike, and those in the interior as well as the inhabitants of the seaport cities. Santiago seems to be the greatest sufferer from both these diseases, especially small-pox.

Hot Weather in England.—There is much suffering in the southern part of England from unusually high temperature, which, however, would not be regarded as excessive here, the thermometer registering only about 80° F. in the shade. A correspondent of *The Lancet* is moved to suggest a practice "which is said to be in common use in Florida and other parts of America" (!). It is, namely, to cool the bed with a tin vessel like a warming-pan, filled with ice. To the English, who have a horror of damp sheets, such a measure would hardly commend itself.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the U. S. Navy for the week ending July 11, 1896. July 7th.—Medical Inspector J. C. Wise detached from the Washington navy yard and ordered as a member of the board of inspection and survey July 15th. Medical Inspector R. A. Marmion detached from the board of inspection and survey July 15th and ordered to the Washington navy yard. Passed Assistant Surgeon S. S. White detached from the naval academy and ordered to the *Thetis*. Passed

Assistant Surgeon G. A. Lung detached from the *Thetis*, ordered home, and granted two months' leave. July 8th.—Surgeon P. A. Lovering detached from the New York naval hospital and ordered to the *Oregon*. Passed Assistant Surgeon C. H. T. Lowndes detached from the Washington navy yard and ordered to the naval hospital at Philadelphia. July 10th.—Surgeon C. U. Gravatt ordered to Norfolk with draft of men and then home with three months' leave. Assistant Surgeon R. G. Brodrick ordered to the *Franklin*.

Government Laboratories in India.—The government of India is about to establish a bacteriological laboratory at Agra and a chemical laboratory at Calcutta.

Trouble in a Brooklyn Hospital.—It is reported that the superintendent of nurses and one of the surgical staff of Seney Hospital in Brooklyn have resigned because of disagreement with the governing board.

An Ether Prize Fund for the Boston City Hospital.—A prize of \$20 is hereafter to be offered semi-annually to the surgical interne of the Boston City Hospital "who administers ether in the most skilful and humane manner."

Physicians are Hazardous Risks.—Several of the accident insurance companies have recently raised the premium rate for physicians, upon the ground that they do not belong in the preferred class, being really extra hazardous risks.

Records of Medical Heroism.—A hall of honor has been established in the Val de Grâce Hospital, in Paris, where the names of French medical men who died in the performance of their duty are inscribed on marble tablets. A list of one hundred and forty-three practitioners has just been placed on its walls, all of whom perished in the yellow-fever epidemic in San Domingo, 1801-1803.—*Medical Press*.

Dr. William H. Welch, of Baltimore, received the degree of LL.D. from his alma mater, Yale, at the recent commencement.

Protection against Law Suits.—It is stated in the *Maryland Medical and Surgical Journal* that a well-known surgeon of Baltimore keeps a book in which he has printed a form which all patients must sign before submitting themselves to an operation while under his care. In the case of a married woman the operation is explained to herself and her husband and both sign the release, and, in case of the absence of a husband, the nearest responsible male relative witnesses the signature of the woman.

A Collective Investigation Concerning Negro Mortality.—The graduates of a Southern college are to make an inquiry into the causes of the large mortality among negroes in cities. It is said that the death rate among negroes in the larger cities of the South is twice that of the whites.

New Jersey State Board of Medical Examiners.—At the annual meeting of the New Jersey State board of medical examiners held at Asbury Park on

July 6th, the following officers were elected for the ensuing year: *President*, Dr. William Perry Watson, of Jersey City; *Secretary*, Dr. E. L. B. Godfrey, of Camden; *Treasurer*, Dr. A. Ubelaker, of Morristown. Resolutions were adopted expressive of the appreciation of the board of the services of Dr. Watson.

Anthrax in New Jersey.—Anthrax has again made its appearance in Greenwich Township, Cumberland County, N. J., where some cows have died of the disease. The disease has also made its appearance at Paulsboro.

Obituary Notes.—DR. WILLIAM A. PIPER died at Philadelphia on July 6th at the age of seventy-seven years. He was born at Milton, Pa., where his father was a prominent practitioner, and he was graduated from Jefferson Medical College in 1844. He was at one time a member of the board of health.—DR. HARRY CLAYTON, a young physician of Middletown, Del., was drowned in Silver Lake on July 6th by falling from a boat in an attack of vertigo. He was a graduate of the University of Pennsylvania.—DR. THERON Z. GIBBS, of Fort Ann, N. Y., was instantly killed at that place, on July 14th, by a railway train which struck him as he was crossing the track. He was sixty-nine years of age, and was graduated in medicine at Castleton, Vt., in 1853.—DR. CHARLES STEYER died at Philadelphia on July 6th from the rupture of an aneurism, at the age of fifty-six years. He was born at Norristown and was graduated from the University of Pennsylvania in 1862. He was for three months in 1861 a volunteer in a Pennsylvania regiment, and upon graduation became an assistant surgeon in another volunteer regiment. In 1867 he entered the regular army as an assistant surgeon and continued in this position until 1878. In 1885 he was appointed a medical officer of the United States Marine Hospital Service at Philadelphia. He was for a number of years one of the visiting physicians to the German Hospital. He was an officer of the Grand Army of the Republic and was connected with a number of other organizations.

Surgeon-Major Heuston, of the British army, professor in the medical school at Tientsin, has been made a mandarin and received the decoration of the Order of the Double Dragon from the Emperor of China.

James M. Anders, M.D., LL.D.—At the recent commencement of Ursinus College the degree of doctor of laws was conferred upon Dr. James Anders, professor of the principles and practice of medicine in the Medico-Chirurgical College of Philadelphia.

Report on the Langerhans Case.—Professor Ehrlich's official report on the serum used in the Langerhans case has been published by the Prussian cultus-minister. Ehrlich comes to the conclusion that the serum was entirely normal in its constitution. He says: "In the Langerhans case No. 216 of the Höchst works was used. This No. 216 had been officially tested on December 16, 1895, and passed on for sale on December 18th, the examination having demonstrated the required one hundred immunizing unities

per cubic centimetre, perfect sterility, and the prescribed admixture of carbolic acid. Immediately after the announcement of the death this serum was subjected to a careful re-examination. As the legal authorities had disposed of the remainder of the bottle used for the injection, samples of the same pass number that had remained at the station were taken, and also bottles of the same number from the stock of the Charité Dispensary, where Professor Langerhans' bottle had come from. The serum again showed the required one hundred unities per cubic centimetre, and bacteriological examination proved it to be free from germs, so that there can be no question of any subsequent formation of poisonous bacterial products. By a number of experiments on animals the admixture of carbolic acid was shown to be no higher than permitted. Thus, on re-examination too, the serum answered to the tests exacted. Nevertheless, it seemed important to ascertain whether, perhaps, toxic effects produced by this number had been noticed anywhere else. About thirteen hundred portions of this serum had been brought on the market, and if it really contained toxic substances it seemed extraordinary that no one had drawn attention to the dangerous qualities of this particular number. Researches were made in the hospitals that had received No. 216 serum from the Höchst works (serum dépôt of the Royal Charité Dispensary, Julius Hospital in Würzburg, General Hospital in Hamburg, sick club of the Royal Dockyards in Kiel, Municipal Hospital in Magdeburg, Krefeld Hospital); in none of these places had any special, much less any toxic, effect of the serum been observed. According to the statement of the director of one of these hospitals, a child of eighteen months had been given a dose of sixteen cubic centimetres, without showing any alarming symptoms. This is at least ten times the dose used for Professor Langerhans' child. The director of the Hamburg Hospital gave an account of immunizing experiments on children. He says that four bottles of the No. 216 serum were used for immunizing children in the eye department; not only were no ill effects observed, but it might be confidently asserted that none existed. Thus the clinical communications also contradict the assumption that substances of strong toxic action were contained in the serum. On the contrary, the No. 216 serum has shown itself to be a preparation answering to all the tests at present exacted, and perfectly normal in its constitution."—*British Medical Journal*.

Philadelphia County Medical Society.—At the stated meeting of the Philadelphia County Medical Society, held on June 24, 1896, Dr. A. J. Downes exhibited "Collapsible and Removable Bobbins for All Forms of Intestinal Approximation; a New Continuous Double-Knot Intestinal Suture; and a New Abdominal Retractor." The bobbins resemble Barnes' uterine dilators and act pretty much in the same way. With the aid of the new suture it is contended that cicatricial constriction at the site of approximation may be avoided. Dr. A. A. Eshner read a paper entitled "Progress in Organotherapy," in which he detailed the many varied applications of organic extracts in the

treatment of disease, and traced the successive steps by which this position has been reached. Dr. Jay F. Schamberg reported a case of "Severe Stomatitis Following the Administration of Potassium Iodide," occurring in a woman fifty-four years old, presenting a syphiloderm of the face and multiple gummata of the tongue. The dose employed was five grains thrice daily, and there was no evidence that mercurials had been ingested.

Pathological Society of Philadelphia.—At the stated meeting of the Pathological Society of Philadelphia, held on June 25th, Dr. A. A. Eshner presented a specimen of carcinoma of the stomach, with secondary involvement of the liver; carcinoma of the liver, gall bladder, and pancreas, probably secondary to carcinoma of the thyroid gland; and an enlarged cirrhotic liver, with an enlarged spleen, manifesting during life symptoms of biliary cirrhosis, although sections shown by Dr. Steele exhibited hyperplasia of the periportal connective tissue. Dr. J. Dutton Steele presented a heart exhibiting stenosis of the tricuspid, mitral, and aortic orifices; and also demonstrated infarction of the kidneys and spleen. Drs. Eshner and Steele presented jointly a specimen of obliterating pericarditis, probably tuberculous; the bronchial glands were anthracotic and tuberculous, and the lungs contained foci of cicatrized tuberculosis; the suprarenal glands were cystic. During life symptoms of Addison's disease had been present. Dr. Joseph Sailer described the changes in the nervous system due to tetanus. These consisted essentially in alterations in the anterior horns of the spinal cord. Dr. W. G. Spiller presented, for Dr. J. Hendrie Lloyd and himself, sections of the cord from a case of subacute paralysis, showing amyloid bodies in great profusion. Dr. A. E. Taylor presented, for Dr. M. H. Fussell and himself, liver, spleen, and specimens stained of blood from a case of leukæmia. He further presented, for Dr. Fussell, specimens of carcinoma of the stomach and liver. Dr. A. Hand, Jr., showed a section of a liver from a case of hypertrophic cirrhosis in an infant.

The Buffalo Medical Journal for June is a women's number, edited by Dr. Maud Josephine Frye, assisted by seven other physicians of the gentler sex. All the original communications are by women, and the items are on subjects relating to professional women. The number is one of great interest and reflects credit upon the able editors. We would suggest that copies be sent, as a missionary enterprise, to some of the conservative old back numbers in London, who are carried once a year to the annual meetings of their societies to squeak out their horror and detestation of women who practise medicine.

Dr. C. W. Stiles, zoologist of the Bureau of Animal Industry of the United States department of agriculture, has been elected honorary member of the Academy of Medicine of Paris.

The Tsar of Russia is an active member and the Tsarina an honorary member of the Russian Red Cross Society.

Obituary.

SAMUEL SEXTON, M.D.,

NEW YORK.

THE death, at his residence in this city, on July 11th, of Dr. Samuel Sexton, although not unexpected by the many friends who were acquainted with the serious character of his last illness, removes from the profession of New York a conspicuous personality. His distinguished position in his specialty made his name well known on both sides of the Atlantic, and gave to his original researches and his earnest advocacy of new methods an authority and influence that were shared by few if any of his peers.

Dr. Sexton was born in Ohio in 1833, and was graduated in medicine from the University of Louisville in 1856. In May, 1861, he enlisted as assistant surgeon of the Eighth Ohio Volunteers, but resigned his commission in October, 1862, and resumed the practice of his profession. After coming to New York he devoted himself to the treatment of diseases of the ear, and was a frequent contributor to the medical press and the author of many brochures. His paper upon the "Causes of Deafness among Public-School Children" was widely circulated in 1882 by the national bureau of education at Washington. This paper won for him from Venezuela, in November, 1889, the medal of honor created by the decree of June 7, 1877, for those who render great service to the cause of public education; and in December, 1890, the same government conferred upon him the highest honor in its gift, the decoration of the "Busto del Libertador." An article in the *MEDICAL RECORD* of February 19, 1887, upon an "Injury to the Ear Caused by the Blast of a Bursting Shell," attracted wide attention among army and navy men as well as among those in civil practice.

Dr. Sexton's most valuable work in otology was the elaboration and improvement of the radical operation of extirpation of the ossicles for the cure of chronic deafness, which was the subject of a paper presented by him to the Otological Society in 1886. In spite of much opposition by his confrères, he eventually succeeded in establishing his method upon a sound basis and in obtaining suitable recognition for valuable pioneer work. He read a paper on the same subject at the International Congress in Berlin, and two years later performed the operation in London at the request of several British otologists. It was not, however, until the appearance of his treatise on "Rare Forms of Ear Diseases" that he obtained the credit that was due him for the large amount of original work he had performed and the great care with which he utilized the vast amount of material at his disposal. He studied his specialty from the broad standpoint of a specially skilled general practitioner, and was always impressed with the necessity of treating the ear as a part only of the general organism. Thus, in his directions for general treatment, he was painstaking to an almost extreme degree, and his numerous consultations with patients from all parts of the world were models of thoroughness, precision, and skill. Full of resources and of original ideas, it was natural that he should be radical in his views and persistent in their presentation. His scholarly paper on the "Treatment of Chronic Catarrh of the Upper Air Passages" exemplifies in a marked degree these special attributes of a broad and well-trained mind. In his intercourse with his professional brethren he was the soul of honor, and although strong in his convictions was ever courteous in their expression, and to all who knew him he presented the well-rounded character of a cultured gentleman.

Society Reports.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Eighteenth Annual Congress, Held at Pittsburg, May 14, 15, and 16, 1896.

PRESIDENT, WILLIAM H. DALY, M.D., PITTSBURG.

First Day—Thursday, May 14th.

President's Address.—THE PRESIDENT in opening the congress called attention to the rapid progress of laryngology during recent years and its present enviable position. He made a plea for the retention of interest by specialists in the problems of general medicine. We have learned, he said, the importance of clearing the upper tract of all obstructions, such as adenoids, enlarged tonsils, etc. Many problems in disease of the accessory sinuses yet remain to be solved. He paid a warm tribute to Manuel Garcia, and spoke of the worldwide sense of loss felt in the death of Dr. Wilhelm Meyer. He welcomed the congress to Pittsburg and expressed his belief that the programme before it had never been equalled in its comprehensiveness by that of any previous session.

Etiology of Deviations of the Nasal Septum.—Paper by DR. JOHN O. ROE, of Rochester. Causes of deviation are predisposing and exciting. The former include diathetic, as strumor, syphilis, tuberculosis, rickets, and cretinism. Civilization increases the liability to deviation, as does also the aquiline type of nose. Deviations are rare among primitive races, especially the Indians, who live an outdoor life and whose mothers fasten their children's mouths so as to develop nasal breathing. Exciting causes are internal, such as defective development and disease of the septum or of other nasal structures. The septum is made up of cartilage and the bony ethmoid plate and vomer. The latter is originally composed of two laminae with an intervening cartilage and begins to ossify at the sixth week of foetal life, though the process is not completed till after puberty, and the union of the laminae is from behind forward. This process is generally completed by the third year but occasionally does not happen at all. Hypertrophy in excess on one side will cause displacement. Disease also of the cavernous tissue of the septum and of the inferior turbinates will produce the same result. Other causes include external injuries, malformations of the superior maxillae, highly arched palate, heredity, and a disproportionate development of the whole face.

Where there is a deflection there is generally a resultant turbinate enlargement on the concave side. This is an effect (not a cause), and is probably due to the excessive amount of air passing through the patent nostril. No one can breathe properly through one nostril alone, no matter how large it may be.

Anterior obstructions may be due to deviated septum, chronic turgescence, growths, operations, dislocation of the triangular cartilage, and flattened alae nasi.

As to trauma, it is frequently an exciting cause, operating more commonly in males of all ages, and is apt to be followed by callus on the convex side. If there is intranasal disease requiring constant expulsion of discharge, the habit of picking the nostril and of blowing the nose constantly with the same hand will operate in the same way.

The Operation for Deviation of the Nasal Septum.—Paper by DR. ARTHUR W. WATSON, of Philadelphia. The author believes that many of the prevalent operations are unsatisfactory because they lose sight of the fact that a deviated septum is longer than

a straight one and make no provision for reduction in the amount of tissue. We must first reduce the septum to a size that will fit into a straight line between the points of attachment of that portion of the nose. This is done by removing a portion of tissue in the general line of deviation. If the latter is horizontal we must take out an elliptical piece gradually convergent at either end; if vertical a wedge-shaped piece should be taken, with apex superior and extending as high as possible, the base reaching to near the base of the septum, where it may be joined by a horizontal incision. The excised portion should always include the protruding angle and the amount of tissue to be removed can be estimated by the eye. We should not cut the mucous membrane on the side opposite the incision, as it helps to hold the edges in line, thus facilitating union and avoiding perforation. Incision should be on the convex side of the septum. To bring the portion into line, some variety of crushing forceps may be used with advantage.

No less important is the second step of the operation (one often neglected), viz., retaining the septum in position. Failure to do this long enough is responsible for much lack of success. Healing of the cartilage requires from three to four weeks. The best support is furnished by a flat ring-head pin, the head being covered with a piece of rubber tubing. The pin should be inserted from the concave side of the septum just back of its anterior edge and passed diagonally through to the other side, then across the vertical incision, if there is one, and then back into the septum until the head lies on the septum within the nostril. Care should be taken not to produce a deflection in the opposite direction. In this way both nares are left free for respiration and cleansing. Padding of the pinhead prevents ulceration, and the pin may be worn for three weeks or more without discomfort.

Should the deviated bony septum require additional support, a pad of iodoform gauze may be placed between the septum and outer wall at the point of deviation, but the bony part heals more quickly than the cartilaginous, and hence the gauze may be removed in from seven to ten days, still leaving the pin *in situ*.

In order to operate properly we must have suitable illumination and the parts must be as free as possible from blood. Cocaine anæsthesia is preferable to ether.

Discussion on these two papers was opened by DR. E. FLETCHER INGALS, of Chicago, who thought that nutritive changes were by far the most frequent exciting causes of septal deviation. He thought the effect of trauma was overestimated.

DR. MORRIS J. ASCH, of New York, agreed with the last speaker as to the overestimation of trauma as an exciting cause. He referred to his own operation presented to the association in 1889. It might leave some intranasal roughness, but it left the nose pervious for respiration.

DR. S. O. VANDER POEL, of New York, had done the Asch operation often. He laid stress upon the necessity of overcoming the resiliency of the septal cartilage. In his hands the pressure of the pin had caused pain and even ulceration. Perforation had sometimes resulted at the junction of the two incisions. Later he had used the Adams forceps to break up the septum, but even then the evil results of pressure from the pin were experienced as before.

DR. CARL SEILER, of Philadelphia, regarded the Asch operation as but a revival of the one proposed by Dr. Glasgow several years ago. He believed that if the pin was placed at the bottom of the septum, the evil results of pressure would be avoided. It should be driven in from the outside at the notch of the nasal bones down to the cleft between the two palatal por-

tions of the superior maxillæ. It should at first be left projecting a little distance above the skin of the nose so as not to be covered in by the swelling of the soft parts.

DR. J. E. NICHOLS, of New York, regarded the Asch operation as good for cartilaginous deviations. All resiliency must be destroyed in cases of bony deviation. He made a compound fracture of the bone and applied the cork splint devised by Berens. He did not believe in the use of the pin unless all resiliency was broken up.

DR. D. BRYSON DELAVAN, of New York, had discarded the pin several years ago. While Dr. Asch may not have devised an entirely new operation, he has elaborated a practical technique. Trauma will not account for all deviations. They may come from mouth breathing, especially that due to adenoids.

DR. W. E. CASSELBERRY, of Chicago, would lay great stress on heredity. No one operation would suffice for all cases. We must take into account the patient's age, mode of anæsthesia, etc. Deviations were chiefly cartilaginous, with some encroachment on the bone. He used as retaining-measures gauze pads and intranasal tubes.

DR. JOHN N. MACKENZIE, of Baltimore, would rise to do a dead man historical justice. The main features of the Asch operation were set forth many years ago by the late Dr. James Bolton, of Bridgeton, Va.

DR. W. K. SIMPSON, of New York, was impressed with the success of the Asch operation. He considered it bad surgery to plug the nares with gauze. He used splints in each nostril at first, but in a few days removed the one on the sound side. The splints were a most effective measure against hemorrhage.

DR. C. M. SHIELDS, of Richmond, noted that many of the deflections were accompanied by thickening on the convex side, and this he first sawed off before straightening the septum.

Some Reflections on Atrophic Rhinitis.—Paper by DR. W. PEYER PORCHER, of Charleston, S. C. After a reference to the various current theories regarding the nature of this disease, he laid down the theory that it was not a disease *per se*, but was a result of other inflammations ending in a purulent discharge which washed away the epithelia and led to destruction of the mucosa.

He narrated the history of a woman, aged thirty-four years, with good antecedent history, in whom scab formation had begun fifteen years before, following an attack of measles. The left inferior and middle turbinates were gone, and those of the right side seriously damaged. Intranasal stimulation and iodides given with a view of increasing secretion were of no avail. Finally the left antrum was opened and irrigated, but without relief to the crust formation. He had finally resorted to a solution of iodine and iodide in glycerin on cotton tampons with a view to causing hyperæmia. This greatly relieved his patients. Crusts were still formed, but they came away more freely.

DR. SEILER regarded the Gottstein cotton tampon as efficacious, even without its being medicated. The secretion it excited moistened the inspired air and the cotton filtered it. He had recently used aseptic wool for the same purpose, but regarded it as distinctly inferior.

DR. THOMAS HUBBARD, of Toledo, had used an alcoholic solution of acetanilid. The proper way to employ the cotton was to wrap it around the turbinated bones.

DR. C. C. RICE, of New York, regarded cleansing and oiling the nose as the essential treatment. We must avoid overstimulation.

DR. G. A. LELAND, of Boston, had used cocaine in ten-per-cent. solution over the turbinated areas for its secondary effect, which was that of congestion. The

addition of resorcin to the cocaine solution obviated the bad systemic effects of the latter.

DR. A. W. DE ROALDES, of New Orleans, had employed electrolysis with cotton-wrapped electrodes.

DR. ROE favored mild silver-nitrate solutions and a mild galvanic current. Scabs do not come from the nasal mucosa alone, but may signify some disease of the accessory cavities.

DR. NICHOLS had used with much satisfaction a solution of orthochlorophenol, in solutions of from ten per cent. up to full strength.

DR. MACKENZIE would protest against the unregulated use of cocaine in the nose.

DR. INGALS did not believe it harmful if the amount in solution did not exceed two grains per week. He had used the yellow oxide of mercury in weak solution in oil, and had been pleased with the results obtained with a one-fourth-per-cent. solution.

Laryngeal Photography with the Aid of the Arc Light.—Paper by DR. THOMAS R. FRENCH, of Brooklyn. In the earlier experiments of the writer in laryngeal photography, the method had several disadvantages, the principal one being the source of illumination, which was sunlight, an uncertain and unreliable agent. Recently he has succeeded in utilizing the arc light, so that good pictures can be taken at any time. Formerly he brought the patient to the light, but now the light to the patient, and results already obtained bid fair to surpass any former ones. Not only the larynx but the naso-pharynx and posterior nares can be pictured.

As the distance between the camera and object to be photographed was very short, one of the greatest difficulties was to adjust the light to the sensitive plate so that a depth of focus would be obtained. To do this, a small diaphragm, a rapid shuttle, a very sensitive plate, and a powerful light are necessary.

The necessary outfit consists of an automatic two-thousand candle-power arc lamp, partly enclosed in a metal box. On the latter's front face is a condensing lens, which at a distance of nine inches from the arc gives a focal distance of twenty inches. The lamp and accessories are fitted to a narrow board on a table sufficiently high. Tilting of the board raises or lowers the light by means of a special device for that purpose. On a shelf beneath the table top is placed the rheostat.

The manner of manipulating the apparatus is the same as with the sunlight condenser.¹

The beam of light should be caught upon the forehead mirror several inches inside the focal point. At first the focus is found, and with it perhaps a good photograph. If, however, a good result is not reached at the first sitting, the focus and the amount of light needed being known, there is no difficulty in obtaining at the second sitting as many pictures as desired. If the apparatus is in good order a picture may be made in as little time as is required for an ordinary careful laryngoscopic examination.

Presentation of Instruments.—DR. INGALS exhibited a portable air compressor so devised that the air pump and spray tube could be folded up within the cylinder. Also a nasal saw with a reversible handle.

DR. SEILER presented a double-screw hook attached to a spiral and covered with another spiral, which acted as a shield. Rotation exposed the hook and caused it to engage in any soft object. It was merely a special application of the principle of the flexible shaft of the dental engine, and could be used to remove soft foreign bodies from the ears and air tract.

DR. ROE presented an improved case of instruments for operation on the nasal septum.

¹ See New York Medical Journal, December 13, 1884.

DR. HUBBARD showed a new variety of nasal wire écraseur.

Recent Progress in the Treatment of Malignant Disease of the Larynx was the title of a paper read by DR. D. BRYSON DELAVAN, of New York. In general, the lives of patients suffering from epithelioma have been shortened, he said, rather than lengthened by the efforts of the surgeon. This statement is based upon the fact that the average duration of life in such cases without removal of the larynx has been a year and a half. Indications are, however, that for operations there is a more promising future. These may be divided into the following classes: 1st, thyrotomy with or without partial laryngectomy; 2d, complete laryngectomy by the Solis-Cohen plan; and 3d, complete laryngectomy in cases of extensive laryngeal disease with glandular involvement.

As to thyrotomy, Butlin has laid down the following propositions:

1st. Every malignant growth of the larynx of intrinsic origin which can be dealt with should be treated by an operation in the absence of a decided indication to the contrary, and operation should be performed with the least possible delay.

2d. Every tumor of the larynx suspected to be malignant, of intrinsic origin, of limited extent, and apparently within easy reach of free removal, justifies an exploratory thyrotomy in a suitable patient, in the absence of infiltration of surrounding structures and of affection of the lymphatic glands. In thyrotomy good illumination must be provided and the parts to be operated upon swabbed with cocaine, in order to contract the blood-vessels and prevent parenchymatous bleeding.

For after-treatment the tampon cannula should be immediately removed from the trachea, the interior of the larynx dusted with iodoform and boric acid, and the patient laid with the operated side down, with one small pillow under the head. The wound is not plugged with gauze, but dusted twice daily as above indicated. The patient may try to drink a little sterilized water while leaning with the upper part of the body bent well over the edge of the bed. If this succeeds, milk may at once be taken.

The advantages of the Solis-Cohen method, in which the larynx is completely removed and the severed end of the trachea secured to the external edges of the cervical incision, are:

1st. Danger to life from inspirative pneumonia is greatly lessened.

2d. Swallowing is as easy as under ordinary circumstances.

3d. In at least three cases power of phonation has been acquired, with a voice fully as satisfactory as that by any artificial appliance.

4th. The patient's comfort is greatly increased, and disfigurement and the necessity for an artificial larynx done away with.

As to the third variety of operation, Cheyne says that, as compared with cancer in the breast, the disease in the throat is in some respects more favorable for cure, in others less so; less favorable because less exposed to view and to operation, but more favorable as regards glandular deposits, for in the neck we have an extensive glandular area freely exposed to view.

Preliminary tracheotomy some few days before the operation is advisable. The patient must not be too old, must have good vitality, must have no physical defect likely to complicate recovery, and must have good surroundings.

In reviewing the recent progress in the treatment of malignant disease of the larynx, it must be apparent that it has nearly all been made by long and close study of the subject by accomplished surgeons. The time has long past when an unsuccessful attempt at

laryngectomy by one not fitted for this work can bring anything but reproach to the operator and discredit to the operation.

DR. PORCHER related his experience with one case and his distrust of the Trendelenburg cannula.

DR. SEILER thought more credit was due to American surgeons than had been given by the reader of the paper, and referred to a case done as early as 1885, by Dr. Roswell Park, of Buffalo.

DR. H. L. SWAIN would lay special stress upon the necessity of removing all the cervical glands. These will sometimes reduce in size after preliminary tracheotomy before laryngectomy is done.

DR. ASCH thought that stuffing the trachea with gauze would answer just as well as the Trendelenburg cannula.

DR. J. WRIGHT, of Brooklyn, would discountenance the performance of these operations by any one except the practised general surgeon.

Intubation in the Adult with Special Reference to Acute Laryngeal Stenosis.—By DR. W. E. CASSELL-BERRY, of Chicago. The adult cannot be treated exactly like the child with reference to intubation, and acute stenosis with its helplessness and exhaustion is not identical with chronic stenosis. The paper discussed four cases of diphtheria, one of acute laryngeal œdema, and one of obscure origin but probably also œdematous. The diphtheria cases all terminated favorably, but presented various difficulties. In one intubation had to be done with the patient in a semi-recumbent position. In another at one time firm spasm of the glottis occurred. In a third three attempts were required to successfully place the tube. All the cases showed some intolerance to the tube. One patient nearly succumbed from accumulation of viscid secretion in the windpipe and larger bronchi below and around the tube. Extraction of the latter removed the difficulty.

The case of acute œdema was complicated by spasm of the masseter muscle. This prevented wide opening of the jaws and intubation failed. Tracheotomy was performed, but the patient died just at its completion, probably from heart failure in connection with pulmonary œdema.

The liability to pressure decubitus in acute laryngeal œdema should be remembered. The other case was probably one of laryngeal and subglottic œdema, and recovered. Conclusions were as follows:

1st. For one accustomed to the laryngeal mirror, intubation in the adult is easier and more certain under its guidance. A sitting posture of the patient should be adopted where possible.

2d. A restless patient may be wrapped in a blanket and seated in a straight-backed chair. The head should be tilted backward and a gag used, with the finger as a guide as in children.

3d. A patient lacking composure and unable to be moved from bed should be placed close to the latter's right edge, so that the operator can stand at the patient's right. The head and shoulders should be well raised by pillows, the neck moderately extended, and the method by the sense of touch otherwise carried out.

4th. In moribund cases the tube may be inserted while the patient is recumbent, the latter being on the right side of the bed and the operator at his right.

Spraying the fauces with cocaine facilitates manipulation. Extraction of the tube is done in the usual way. The author's posture method of feeding subsequent to intubation is carried out with greater difficulty in adults than in children, on account of the difference in size and weight. The author's experience seems to justify the statement that in the diphtheria of adults intubation may advantageously be substituted for tracheotomy. So also in acute œdema, un-

less the exhaustion is extreme, a single attempt may be made. The smallest-sized adult tube should be used in order to avoid pressure decubitus. In cases of "set-jaw," or pharyngeal swellings, intubation is contraindicated. It is permissible in laryngeal arthritis deformans, traumatic œdema, laryngismus stridulus, and in œdema secondary to chronic specific or tuberculous disease.

DR. SIMPSON said that the word "acute" should be used with some reservation, because there was a vast difference between the acute stenosis of diphtheria and that engrafted upon a chronic inflammation, as the œdema of Bright's disease or other stenosed conditions, which were not sufficient to impede breathing. The tongue should be well drawn forward.

DR. HUBBARD had seen two cases of acute œdema of the trachea while the larynx was normal. In tracheal stenosis intubation would be unsuccessful. He had tried tracheotomy in one case unsuccessfully. The condition was caused by erosions following specific ulceration. The second case was one of iodine poisoning, in which there was œdema not only of the trachea but of the face and pharynx, while the larynx escaped. It was only relieved by pilocarpine.

DR. ROALDES believed that intubation was useful in fracture of the larynx.

Spindle-Cell Sarcoma of Nose; Specimen and Slides.—Case reported by DR. J. E. BOYLAN, of Cincinnati. Paper read by title. The patient was a male who complained for several months of severe nose bleed, obstruction, and occasional acute pain: noticeable bulging was seen under the left nasal bone. On tilting up the end of the nose a red liver-like mass was seen, occupying the entire nostril and limited behind by the posterior nares. By the wire *écraseur* the growth was removed in two pieces and the base curetted. Hemorrhage was profuse, but was controlled by plugging with iodoform gauze.

The tumor was as large as a hen's egg and the attachment, about one and one-half inches long, appeared to be confined to the inferior turbinate. Examination showed spindle-celled sarcoma. There was no recurrence after twenty-two months. The paper closed with a list of cases reported since Bosworth's tabulation of 1889.

Naso-Pharyngeal Fibrous Tumors.—Paper by DR. F. FLETCHER INGALLS. The case was reported of a boy aged eleven who, ever since his fourth year, had had a fulness of the cheek associated with nasal stenosis. His general condition was good; the voice had a nasal twang, sense of smell was deficient, and there was a mass filling the left nostril and pushing over the septum, extending back and attached to naso-pharynx. This was removed under cocaine and the galvano-cautery *écraseur*. There was considerable hemorrhage, checked by plugging with surgeon's lint steeped in saturated solution of iodoform in ether and then in boric acid. Subsequent cauterizations removed all traces of the mass but caused considerable cicatricial tissue in the vault. The swelling in the right cheek was treated with submucous injections of twenty-five per cent. of lactic acid and two or three per cent. of carbolic acid in twelve per cent. of glycerin. These injections caused the disappearance of two-thirds of the tumor. The writer advocated this measure in cases in which the knife or galvano-cautery was inapplicable.

Naso-Pharyngeal Fibromata.—This was the title of a paper by DR. CHARLES M. SHIELDS, of Richmond, who reported two cases with exhibition of slides and photographs.

CASE I.—Male, twenty-three years. Growth firm, filling naso-pharyngeal space and left nostril, attached to pharyngeal vault and partly its posterior and left lateral wall; also to outer wall of left nostril for half

its length. The growth crowded the nasal septum to the right, completely occluding the latter nostril, causing typical "frog face" and "dead" voice. Under ten-per-cent. cocaine injected hypodermatically into left nostril, a bougie carrying a silk thread attached in turn to a sharply bent loop of cold wire was worked through the nostril down into the throat and out through the mouth. The wire was then fashioned into a well-rounded loop and the nasal ends threaded through the cannula of a snare and tightened. Gradually increasing tension was exercised for five hours, when the wire broke. The next day a galvano-cautery snare loop was applied in a similar manner, and the growth quickly severed. It measured one and one quarter by one and two-fifths inches. Some fourteen months later a fragment the size of a grain of corn was removed from the left nostril and some thickening was found at the site of the main tumor in the pharyngeal vault.

CASE II.—Woman (negress), aged forty-eight. (Many writers have claimed that women are exempt from this class of diseases. Dr. Shields had never seen a similar case in a negro.) The tumor filled the entire naso-pharynx, pushing the palate well forward, but with no nasal attachment. Electrolysis faithfully tried for six weeks gave little result. Microscopical examination of a fragment removed showed true fibroma. Dr. Shields thought that but very few (if any) of such growths could not be reached through the natural passages and consequently that resection of the superior maxilla was rarely required. He regarded as unworthy of consideration ligatures, caustics, thermo-cautery, and evulsion. The hot or cold snare would generally answer. The use of irido-platinum wire is to be preferred on account of its stiffness, or the hot snare. The current should be used interruptedly, with time for the patient to rest between its applications. Pain is thus minimized and hemorrhage avoided. Moreover, the cold wire will sometimes break. In tumors with a broad base a groove can be made by a preliminary heating of the irido-platinum wire, thus preventing slipping of the latter. Finally, this mode of treatment effectually cauterizes the base of the growth.

DR. CASSELBERRY remarked that in operating on this class of tumors it was often advisable to slit up the mass with the cautery knife, so as to afford a hold for the wire. He believed also in the utility of electrolysis for these growths.

Tuberculous Infection of the Lymphoid Tissue of the Pharynx, with Some Remarks on Laryngeal Infection.—Paper by DR. JONATHAN WRIGHT, of Brooklyn. This paper was intended as an addendum to the paper read by the author at the congress of 1895. He repeated Dieulafoy's experiments in twelve unselected cases, inoculating guinea-pigs with tonsils and adenoids, which in each case were examined histologically and bacteriologically, with negative results. The animal experiments made by Dr. W. H. Park also resulted negatively. Tubercle bacilli having been found by Strauss and others in healthy noses and throats, Dr. Wright is inclined to think that Dieulafoy's results were due (as Cornil suggests) to surface contamination. Results similar to those of Dr. Wright have also been published by Ricardo Botey, of Barcelona.

Reference was also made to a case seen by Dr. W. F. Chappell, of New York. The patient had tuberculosis of the naso-pharynx following an operation for adenoid. Tissue taken from this patient and subjected to the same methods of examination as in the twelve unselected cases was found to contain tubercles and tubercle bacilli histologically, while Dr. Park by animal inoculation also obtained positive results. This goes to prove that Dr. Wright's methods were not at

fault in the twelve cases that were supposed clinically to be non-tuberculous.

In taking sections of tissue from a tuberculous larynx Wright found indisputable evidence of the penetration of intact epithelium by the bacilli, but he is not prepared to say whether this is possible in healthy throats.

The Relation of Diseases of the Nose and Throat to Disorders of Digestion—Acute Diseases of the Nose and Throat.—Paper by DR. H. R. BROWN, of Chicago. Pharyngeal hyperæmia is frequently present in stomach cough. Asthma frequently results from digestive disturbances. Angioneurotic œdema of the larynx, laryngeal hemorrhage, attacks of unconsciousness in laryngeal phthisis, hemorrhagic affections in hepatic cirrhosis are all caused by disorders of the gastro-intestinal tract. Swallowing secretions from sores often upsets the stomach. A distended stomach by upward pressure on the diaphragm may cause glottic spasm. In typhoid fever laryngeal complications are not at all infrequent. There is, however, no direct proof that disease of the upper air tract is caused by gastric disturbances, but clinical experience strongly suggests that this is true.

Chronic Disease of the Nose and Throat.—Paper by DR. T. R. FRENCH, of Brooklyn. Chronic nose and throat disease is often associated with digestive disturbances, but we cannot always demonstrate the relation of cause and effect. Many causes of catarrhal disturbances act by first influencing the digestive organs. The writer alluded to observations made on fifty medical students, all of whom had pharyngeal and faucial catarrh. In forty-seven there was digestive disturbance, fourteen were constipated, only one had a clean tongue, forty-five were rapid eaters, thirty-three smoked, sixteen had nasal obstruction, and two were mouth breathers. The smokers did not seem to have any worse pharyngeal condition than the non-smokers. In twenty-three cases of gastric disturbance in women, half of whom were distinctly neurotic, all had pharyngitis, four had clean tongues, four nasal obstruction, four had additional mouth breathing. The portion of the gastro-intestinal tract affected did not seem to have any bearing on the pharyngeal condition. Disorders of the stomach and bowels often produced reflex vasomotor disturbances.

DR. CASSELBERRY remarks that Türk had found the same bacteria in the stomach as in naso-pharyngeal secretion. By curing the pharyngeal disease we would cure the stomach condition also.

Case of Gun-Shot Wound of the Pharynx.—Reported by DR. D. N. RANKIN, Alleghany. A man was shot in 1847 in the pharynx, the missile passing in on the right side about two inches below the lobe of the ear, going across the pharynx and coming out at a corresponding point on the right side. Nothing could be learned from the patient as to the occurrence of hemorrhage or difficulty in deglutition after the wound. The latter cicatrized on both sides and the man lived nearly fifty years.

Second Day—Friday, May 15th.

Contribution to the Pathological Anatomy of Ethmoid Disease.—Paper by DR. JOHN N. MACKENZIE, Baltimore. The writer related several clinical histories of the ordinary type of the disease and gave detailed pathological reports upon the tissue removed from the ethmoid region. The tissue showed evidence of chronic inflammatory changes similar to all intranasal inflammations, the glands having been gradually destroyed by invasion of leucocytes and by the contraction of the fibrous tissue resulting from the inflammatory changes. To the tissue removed in such cases the name of myxomatous tissue was generally

given. The writer would take exception to such an application of this term. He advanced the following propositions:

1. So-called myxomatous degeneration is not in reality a mucoid change at all, but a simple inflammation. The word "myxomatous" is used in a loose sense. The nasal chambers are in reality the last place in which we would naturally look for a mucoid change. Myxomatous polyps are in reality only œdematous fibrous tissue, not myxomatous. They represent chronic degenerative destruction by round-celled infiltration and fibrous changes, and are a legacy of simple inflammation. He would suggest the term "endorrhinitis" as applicable to such cases.

2. Our usual method of using the term myxomatous is erroneous, because the question is approached from the clinical side alone and the tissue removed is rarely examined microscopically.

3. Ethmoiditis, even though purulent, may last for years without causing any bony lesion. Yet many writers intimate that caries and even necrosis are very frequent accompaniments. A primary original necrosis in these cases has not been established. Pent-up secretion may cause osteitis but not necrosis. He did not believe that nasal polyps ever arose from necrotic bone.

4. The various changes found represent successive stages of the same affection and hence a variety of names is not necessary.

5. A marked similarity exists between the granulation tissue and sarcomatous tissue. Hence we must examine different portions of the masses removed before forming our conclusions.

Sero-Purulent Maxillary Sinusitis in Chronic Lead Poisoning.—Paper by DR. H. L. WAGNER, of San Francisco (read by title). Patient was a male of thirty-two and for twelve years a carriage painter; family history negative. He had complained for three years of severe right supra-orbital neuralgia. Pains occurred daily at intervals of from one to twelve hours. He had hyperosmia, all strong odors producing an attack. Various opiates and coal-tar derivatives had failed to give relief, as had also resection of the right supra-orbital nerve. All teeth in the upper jaw, some decayed, had been extracted without improvement in the patient's condition.

Examination showed a well-built man with yellow skin, flabby muscles, no syphilis, eyes and ears normal, and slight dry pharyngitis. Left nares normal. On right side was slight hypertrophy of middle and lower turbinates. At entrance of hiatus semilunaris a daily crust formed, easily removed, and a slight sero-purulent discharge (containing staphylococcus aureus and a few non-pathogenic cocci) could be observed only every second or third day. Transillumination showed little difference between the two sides; face not swollen externally. No pain was felt from pressure over supra-orbital region. Right upper gum was hypertrophied, but no blue lead line visible. Pressure on region of right first molar caused severe neuralgic pain.

A diagnosis was therefore made of right antral trouble. The antrum could not be probed or irrigated through the hiatus, and Dr. Wagner therefore perforated through the hard palate. The injection of warm sterilized water was followed by a sero-purulent discharge from the nostril. The antrum was then opened with a large trephine through the canine fossa under chloroform anæsthesia. The cavity showed in the lower and side walls a peculiar grayish-blue hypertrophy of the mucosa. Probing revealed no caries, but pressure in certain places caused great pain. Examination of a bit of the hypertrophied mucosa showed loose connective tissue infiltrated with much serum and a fair number of round inflammatory cells, the tissue being cov-

ered with columnar epithelium and containing some micrococci.

After thorough removal of the tissue dry treatment with borated gauze gave no relief and other methods were also unsuccessful. The urine was then examined, but no albumin, sugar, or lead were found. Fresh tissue from the antrum, however, gave the characteristic lead reaction with sodic sulphate. Under the iodide treatment all pain disappeared after a few days, as did also the crust formation and sero-purulent discharge. Traces of lead were later detected in the urine.

The writer believes that in his case the antrum disease, including the neuritis of various nerves, must be ascribed to the deposit of lead, perhaps as an albuminate. Similar conditions have been observed in a few eye cases in which optic neuritis with severe cephalalgia was caused by chronic plumbism.

Study of Irruption of the Teeth into the Nasal Chambers.—Résumé of reported cases and report of additional cases. Paper by DR. A. W. MACCOV, Philadelphia. The writer gave a complete bibliography to date of this class of cases and related some of his own. Teeth in the nose may cause not only local irritation and purulent discharge but also reflex cough and laryngeal spasm. In one of his own cases, in the examination of the nostril in a case of sarcoma, the presence of a tooth in the nostril was accidentally discovered, and the question suggested itself as to whether such presence may not have been the exciting irritation which eventuated in malignant formation.

Control of Hemorrhage in Operations on the Nose and Throat.—By DR. A. COOLIDGE, JR., of Boston. In undertaking any operation under an anæsthetic, the position of the patient is a first consideration. The customary horizontal position is frequently contraindicated because it is possible that blood may enter the pharynx or larynx. When the operation is confined to the nasal cavity, such an accident may be headed off by the preliminary plugging of the posterior nares. The Rose position (head hung perpendicularly over the end of the table) is to most operators awkward, though it prevents escape of blood into the lower pharynx. The Trendelenburg position protects the trachea from blood in thyrotomy and operations on the lower pharynx. For operating, however, on the upper respiratory tract, advocacy is made of setting the patient in a chair opposite to the surgeon. If the body be inclined well forward, blood from the mouth or nasopharynx flows well outward. Of course, the patient must be under absolute control. This position is consequently more satisfactory with children than with adults.

To check hemorrhage compression if possible is to be preferred. Styptics are unreliable, irritating, and cause loss of time.

Nasal hemorrhage can generally be stopped by plugging the anterior nares, and every rhinologist should know how to do this thoroughly and well. Nasopharyngeal hemorrhage can be controlled by filling the cavity with gauze from below—just as we plug the posterior nares. The amount of bleeding depends on the size and number of vessels which may enter the part removed and the amount of contraction which is allowed by the structure of the intervacular tissue. Troublesome bleeding is seldom met with in adenoids, tonsils, and myxomatous growths. The reverse happens with sarcoma and fibroma attached to the basilar process. To control hemorrhage from the latter, immediate firm plugging both anteriorly and posteriorly should be done. In the adenoid cases less blood is eventually lost with the curette than follows the application of the forceps. In tonsillotomy the cold-wire snare with general anæsthesia, or the hot-wire snare with cocaine, will generally prevent bleeding.

Intermittent Dysphonia Spastica.—By DR. F. I. KNIGHT, of Boston (read by title). Dr. Knight reviewed briefly what is known in regard to this affection, which in its well-marked chronic form he continues to think very rare. He added a report of a recent case, in order to call attention to the intermittent character of the affection. The patient was a clergyman and the attack manifested itself only during the latter half of a sermon. This was presumably on account of fatigue. It appeared suddenly after the gentleman had spoken in a perfectly normal voice for an indefinite time. Dr. Knight said this was the only patient of the kind who had consulted him who did not unmistakably betray his affection during the interview.

A Case of Unusual Laryngeal Growth.—By DR. J. W. GLEITSMANN, of New York. The patient, a Russian Jew, aged thirty-eight, had suffered from hoarseness for one year, but without emaciation, pain, cough, dyspnea, or cervical adenopathy. The larynx showed on the right side a snow-white mass extending from the anterior commissure to the arytenoid cartilage. It seemed to lie between the true and false cord, looking very much like a bunch of cotton stuffed into the ventricle of the larynx. Its surface was slightly corrugated and its border a little irregular. The movements of the right side of the larynx were apparently normal. Adduction was perfect. Otherwise the organ seemed free from disease.

By means of a Landgraf's double curette a piece was excised, but it proved to be too superficial for satisfactory microscopical examination. Bleeding after operation was slight, and there was no special reaction. A fortnight later a second and larger piece—about one-fourth of the whole growth—was removed, and reported after examination to be a hard papilloma of the larynx, probably malignant and possibly carcinomatous. It was made up of a proliferated papillary mucosa with a thickened epithelial covering, apparently horny on the outside. The underlying epithelia were greatly proliferated and the nuclei split up. In consequence of connective-tissue proliferation there was a small-celled proliferation of the submucosa. The epithelial layer showed a tendency to invasion of the subepithelial tissues as in carcinoma.

The marginal glands were also changed. The cylindrical epithelia appeared to merge from one follicle duct to another, instead of being distinctly separate, as under normal conditions.

The patient disappeared from view after the second operation, and the later history is unknown. The writer of the paper had found no reference in literature to a tumor of the snow-white color this one presented. Such a color was to be regarded as strongly suggestive of malignancy. Cancerous growths did not by any means produce in their incipency hyperæmia or inflammation of the cords.

A Report of Cases of Tuberculosis of the Larynx, with Results of Treatment as Far as Ascertained: The Topical Use of Bromoform, Formaldehyde, Guaiacol, and Protonuclein.—By DR. S. SOLIS-COHEN, of Philadelphia. Dr. Cohen related the clinical histories of several cases, advocating especially the use of formaldehyde. His plan is to cleanse the larynx with a spray of hydrogen peroxide, followed by alkaline detergents. The formaldehyde occurs commercially in a forty-per-cent. solution, known as formalin. A ten-per-cent. solution of formalin therefore equals a four-per-cent. solution of formaldehyde. Water is used as a diluent, but as the solutions do not mix well extemporaneously it is well to have them prepared and kept on hand. Cocaine is first applied in four-per-cent. solution, and then two- to ten-per-cent. solutions of formalin rubbed in according to the tolerance of the patient and the progress of the case.

A slight burning pain was generally felt, lasting, however, only two or three minutes. Dr. Cohen has found that it reduces cough, as does also bromoform. The latter produces a certain amount of local anæsthesia.

DR. GLEITSMANN called attention to good results obtained by him with parachlorphenol. It produced a shrivelling and absorption of infiltration not obtained from lactic acid, which was better adapted to ulcerated surfaces. Two-per-cent. solution was strong enough, and in order to prevent stickiness therein he mixed the remedy in equal parts of glycerin and water.

Some of the Unusual Manifestations of So-called Catarrhal Laryngitis.—By DR. C. C. RICE, of New York. The following views were advanced:

1st. There are two ordinary types of catarrhal laryngitis—one following and dependent upon nasal obstruction, and the other upon a laryngitis sicca, an extension downward of atrophic rhinitis and dry pharyngitis. In these two processes the same pathological condition exists from the commencement of the nose to the bronchial tubes.

2d. Laryngeal disturbances occasionally occur, which from their appearance might belong to one of these two ordinary types, but the significant point is that they are present when the nose and pharynx are in excellent condition, or, still again, the laryngeal disorder, although in kind like that of the nose, is much greater in degree, which is the reverse of the usual condition.

3d. There are several disturbances, usually classified under "catarrhal laryngitis," which seem to bear little or no relation to a previously existing nasal or pharyngeal disease. They are commonly observed in singers and public speakers, and are undoubtedly caused by overuse of the voice and improper methods of breathing and of tone production.

4th. We also find:

(a) General tissue atrophy of the soft parts of the larynx and pharynx, which produces a disordered relation and a general muscular weakness of the larynx.

(b) Permanently enlarged and usually congested epiglottis, the larynx as a whole being normal.

(c) "Choked voice," caused by actual enlargement of the ventricular bands.

(d) Permanent and perhaps congenital vascularity of the vocal bands.

(e) Localized congestion of some portion of the larynx, indicating probably overuse of the transverse arytenoides, or possibly of some muscular group.

(f) "Singers' nodes," from incorrect vocal methods, and cured by proper breathing and singing.

(g) Muscular fatigue with hoarseness or aphonia.

5th. These various disorders should be recognized by proper names, their etiology appreciated, and they should not be confused with the phenomena of a simple catarrhal laryngitis.

6th. Little dependence can be placed upon topical treatment, unless special care be given to proper methods of breathing and voice production.

DR. ROALDES had noticed redness of the cords, especially in basses and baritones. He thought the condition more common in patients of gouty and rheumatic tendencies. The condition was less frequent in tenors and sopranos.

DR. SIMPSON called attention to the fact that few singers escaped more or less laryngeal trouble, and he had sometimes been led to think that singing was an unnatural use of the voice.

DR. NICHOLS had observed persistent redness of the cords in an alto singer, who nevertheless sang perfectly.

Report of a Case of Incomplete Fracture of the Left Cornu of the Thyroid Cartilage, Resulting from Self-Inflicted Violence.—By DR. A. W. DE ROALDES, of New Orleans. The patient, a man aged

thirty-seven, swallowed an olive seed. He experienced a sense of a foreign body in the throat, and manipulated the latter violently from the outside in trying to dislodge the seed. The sense of a foreign body disappeared, but the patient felt at the same time a creaking sensation in the throat. The next morning nothing could be seen except a projection on the inner side of the throat, without any marks of external violence. The mucous membrane over the site corresponding to the left cornu of the thyroid seemed to be poked inward by something underneath. The report concluded with an enumeration of the anatomical points which led the writer to regard the affection as one of the thyroid cartilage rather than of the hyoid bone.

Perichondritis of the Crico-Arytenoid Joint from an Unusual Cause.—By DR. H. S. BIRKETT, of Montreal. The case was reported of a young man who in the course of a gonorrhœal attack had inflammatory joint trouble, affecting the ankle, knee, and shoulder of the left side. In the course of this a soreness and difficulty in swallowing was experienced on the corresponding side only of the throat. Examination showed the mucosa over the left crico-arytenoid joint swollen and œdematous. The left aryepiglottic fold was not swollen. The true cords were white, and the abduction and adduction of the left one were decidedly slower than the corresponding movements of the right. Outside pressure over the affected joint was painful. Voice was hoarse. Treatment consisted in applying the ice-water coil, affording great relief.

Third Day—Saturday, May 16th.

The Sequelæ of Syphilis and Their Treatment.

—The discussion was opened by DR. C. H. KNIGHT, of New York, who spoke of the sequelæ and treatment of syphilis as affecting the nose. He said that it is not always easy to diagnose late nasal syphilis. It is often mistaken for sarcoma, and excision of the upper jaw needlessly advised. The grade of severity of symptoms depends on the fact as to whether only the soft parts are involved or whether the hard parts are also affected. Syphilis is responsible for some septal perforations, but by no means for all. When the bone is involved we have two problems to solve: 1st, when and how to remove dead bone; and 2d, how to remedy resulting deformity. The writer advocates conservatism in dealing with sequestra unless they are quite detached and accessible.

If dead bone is firmly attached or embedded, or if we cannot accurately define its limitations, or, again, if it is high up in the nasal cavity in the ethmoid region, we must approach it with great caution. The Rouge operation enables us to remove large sequestra when they are loose and of extreme hardness.

External deformity from loss of cartilage is frequently slight, but when the bone is destroyed the deformity is often hideous. For these cases the writer advocated the Martin platinum bridge.

Several cases were related in detail. This method is believed to be an excellent one with certain precautions. The active stage of the disease must have been long passed, and the patient must have had radical treatment. The bridge must be so constructed and shaped as to avoid friction and pressure. The dissection of the soft parts must be wide enough to obviate tension after the bridge has been placed in position. The writer, in closing, alluded to the use of a simple plate of platinum slipped under the skin of the dorsum nasi, the dissection in preparing a bed for the bridge having been made through the nostril. This plan is much simpler and is equally effective in moderate deformities.

DR. J. E. NICHOLS, of New York, continued the dis-

cussion, speaking of the question as it concerned the pharynx. It mattered relatively little how severely the uvula and tonsils might be affected, but it was quite another matter when we came to consider lesions of the soft palate. The epiglottis might be partly or even wholly destroyed without causing much trouble. If adhesion of the pharyngeal mucosa occurred to the inferior portion of the posterior faucial pillar, there were apt to be difficulty in deglutition and impaired movements of the tongue.

When the soft palate is at all adherent to the pharyngeal wall great care should be taken to avoid all caustic applications, which aggravate the very condition they are intended to relieve. The iodides should be systematically given.

When complete adhesion occurs the patient becomes, perforce, a mouth breather. The voice is affected, and traction from cicatrization upon the orifices of the Eustachian tubes is apt to develop aural complications. There is more or less danger of otitis media, muco-pus accumulates in the naso-pharynx, and anosmia comes on.

The writer then referred to the various means which have been tried to remove these adhesions. These include the cautery, knife, and subsequent digital or instrumental dilatation. No matter how deeply we may incise or how thoroughly dilate, cicatrization is apt to advance from below. He then described an operation devised by himself some years ago and subsequently reported, in which the adhesion bands are operated upon on the same general principle as is followed in the surgical treatment of "webbed fingers." He believed this operation to be practicable in every case, for there was no case on record in which the naso-pharynx was entirely shut off by adhesion from the oro-pharynx. The opening might be difficult to find and might be so small as to admit only a fine probe.

DR. W. K. SIMPSON, of New York, discussed the question as affecting the larynx. He drew attention to points of difference between the "sequelæ" of syphilis and the significance of the term as applied to other diseases. In syphilis they are to be expected and vary only in the length of time of their occurrence and in their nature. True sequelæ are those resulting from tertiary manifestations, and find their best expressions in chronic thickening, loss of substance from ulcerations and broken-down gummata or from perichondritis, falling-in of laryngeal walls from loss of cartilage, and ankylosis of various articulations, paralysis, and various deformities.

The two leading conditions produced are loss of voice and laryngeal stenosis. Aside from sequelæ resulting from structural change, there is often a hyperæmic condition which interferes with a perfect control of the voice, noticed especially in singers. This condition is liable to come on from overuse, exposure, sudden climatic changes—affecting, consequently, sailors, etc. Moreover, smooth intralaryngeal swellings may mask an underlying gumma, and hence the difficulty of intubating such cases.

Attention was next called to the difficulty of differential diagnosis between syphilis, tubercle, rheumatism, and malignancy. Without the finding of tubercle bacilli we can never be sure of tubercles, however strong the other points may be. Illustrative cases were quoted.

In the treatment the writer referred to the general use of the iodide and mercury, either alone or in combination, mentioning the recent paper of Irsai, who advocates intramuscular injections of bichloride directly at the site of the lesion. When stenosis is absent this general treatment is sufficient. When stenosis exists some mechanical treatment is necessary, either tracheotomy or some form of dilatation. Allu-

sion was made to the unsatisfactory results with the Schrötter instrument. Not until we had the O'Dwyer tube at our disposal were we convinced of the tolerance of the larynx in these cases to long and continued pressure, which is the main feature sought in bringing about a cure. The pressure of the intubating tube undoubtedly causes absorption of morbid tissues and wears out the tendency to recurrence of the stricture.

The author then laid down the general rules of technique for intubation in this class of cases.

The discussion was continued by DR. JOHN O. ROE, who said that the most serious nasal cases were those of hereditary syphilis. The cartilage disappears and often the bone, sometimes even the nasal bones themselves, so that there is a sulcus or cavity where the nose ought to be. In adults the disease was generally confined to the cartilaginous septum. Abscess frequently occurred and the sesamoid cartilages might be destroyed. He then described a subcutaneous flap operation, designed in these cases to restore the symmetry of the nose.

DR. ROALDES was opposed to the Rouge operation alluded to by Dr. Knight. As good results can generally be obtained by intranasal procedures. The drill can be used to pierce the sequestrum in different directions, and the latter can then be crushed.

DR. E. FLETCHER INGALS had found syphilitic ulcerations of the cartilaginous septum rare, unless the bony septum was also involved. Of perforations of the former, probably not more than ten per cent. were syphilitic. In giving the iodide in tertiary lesions, the dose should be gradually increased up to the maximum and as gradually decreased, then increased again, and so on. In this way the large amounts of the remedy so frequently needed would be much better borne.

DR. W. PEYER PORCHER called attention to the condition of the nose in leprosy as contrasted with syphilis. In treating the latter he was partial to mercury controlled by minute doses of opium.

DR. THOMAS HUBBARD, of Toledo, believed that mercury was liable to increase the destruction of cancellous bone, unless the parts could be kept thoroughly disinfected.

DR. D. BRYSON DELAVAN said that he had had one case in which there was total occlusion of the naso-pharynx from the oro-pharynx by adhesions. He called attention to the risk in operative procedures of both primary and secondary hemorrhage.

A Case of Fibro-Chondroma of Branchial Origin, or So-called Supernumerary Ear, Removed from the Throat of an Infant Six Weeks Old.—This case was reported by DR. A. W. DE ROALDES, of New Orleans. The family history in the case was negative. Immediately after the birth of the child a queer noise was noticed in its breathing and it seemed to have attacks of partial strangulation. These were ascribed to phlegm and croup, but an examination by the reporter of the infant's throat disclosed the presence of a growth. The child's external ears were normal in appearance. When it cried the growth seemed to come down from behind the palate. On continued crying it seemed to descend still farther to the aditus laryngis; finally, it would assume a third position on the dorsum of the tongue. It was noted that its covering was of a cutaneous (not mucous membrane) character. The naso-pharynx seemed to be free. The attachment was made out to be to the left posterior pharyngeal pillar. It was removed by evulsion and contained cartilaginous nodules, appearing in general like a supernumerary ear. The microscopical examination showed its outer covering to be identical in its histological elements with the true skin. The mass also contained fat and connective

tissue, and a diagnosis was made of branchial chondro-fibroma.

Acute Disease of the Lingual Tonsil.—DR. HENRY L. SWAIN, of New Haven, said that apparently not much had been written on this subject, but if he was to judge by his own experience during the last three years, the condition had formerly been overlooked by him. In any case he had persuaded himself that acute lingual tonsillitis was often the cause of symptoms referred to other parts of the throat, simply because the latter were more frequently the seat of disease and more easily accessible to view.

The anatomy of this region makes it evident that the inflammation is rarely of the peritonsillar type. The symptoms of the varieties of lingual tonsillitis were then described. The writer recognized three forms of the malady, the simple, the follicular, and the peritonsillar. Symptoms were the same in kind as in other acute throat affections, modified by the difference in the locality affected. Persistent cough is a frequent and troublesome feature. The larynx is often blamed therefor, while the lingual tonsil is at fault.

If the deeper tissues are affected the symptoms assume a severer type. The epiglottis and even the glottis may become involved. Life may become endangered and even tracheotomy may be required.

As to treatment, he preferred applications of glycerite of boroglycerin followed by a powder of tannin with the addition of a little morphine. Hot demulcent gargles were a valuable adjuvant. Systemic remedies were indicated as in the ordinary forms of tonsillitis.

The paper closed with the history of a case of abscess of the lingual tonsil slowly developing after an ordinary faucial tonsillitis. The attack was ushered in with a sharp attack of œdema of the glottis. The abscess had formed close to the aryepiglottic fold and had broken well back toward the arytenoid cartilages.

Treatment of Simple Acute Laryngitis and Bronchitis.—PAPER BY DR. THOMAS HUBBARD, of Toledo. The existing literature on the use of expectorants is full of inconsistencies and much of the treatment advised is irrational. Stimulating expectorants, fortified by opiates and local palliative treatment, are quite too popular to the unwise exclusion of a judicious use of relaxing expectorants.

Attention is called to the essential features of acute inflammation of the middle respiratory tract. Bronchial hyperæmia with more or less swelling produces a condensation of the cellular elements, since the same number of epithelial cells occupy smaller areas in proportion as the calibre of the tube is lessened. This is one reason why it is so difficult to re-establish the mucous flow, the outlets from the glands being thus closed. Retained mucus ferments and becomes acid and irritating, whether within the substance of the membrane or on its surface.

The first indication then is to re-establish the mucous flow. The best relaxing expectorant is apomorphine, given in one-thirtieth-grain doses every two to four hours. Except in severe cases and debilitated persons the subsequent use of stimulating expectorants is rarely necessary. The proper use of relaxing expectorants greatly lessens the need for opiates. All forms of abortive treatment are deprecated.

Squamous Epithelioma of Velum Palati Cured by Injections of Caustic Potash.—DR. HUBBARD also reported the following case: The patient, a male, had suffered for more than a year from a mass, of flat, tabular type, situated partly in the velum palati and partly in the right anterior faucial pillar. All internal and local treatment had been without avail. Cocaine habit had become established. In August, 1894, he was on the verge of collapse from malnutrition,

being able to take only a small quantity of milk and ice cream. The cocaine habit was first cured, but the pain incident to deglutition could not be relieved. With a curved platinum needle caustic-potash injections destroyed a conical-shaped tumor mass. Whenever proliferating epithelial growths were seen around the edges the injections were repeated in lesser amounts. Cicatrization and improvement in general health rapidly ensued. The patient gained forty pounds in two months. Up to two years after the first injection there had been no return of the growth.

Sarcoma of the Nasal Chambers and Accessory Sinuses.—DR. A. A. BLISS, of Philadelphia, reported two cases of this kind.

CASE I. Child of four years with negative family history. At the age of one year its left nostril was observed to be occluded by what the attending physician called polypi. The tissue was removed, but recurrence had taken place in the course of six days. During the ensuing eight months the nostril was cleared out no less than thirty times. When seen by Dr. Bliss the left nostril was occluded and the septum was deviated to the right. There was no swelling over the antrum. The left eyeball was protruded. There was no glandular enlargement. The antrum was opened and found filled with a fungoid mass. The orbital roof was found intact. The post-nasal space into which the growth had extended was cleared out by the finger and cutting forceps. There was considerable hemorrhage, which was stopped by stuffing with iodoform gauze. There was no recurrence, but in six weeks the glands under the jaw became enlarged and symptoms ensued suggesting involvement of the respiratory centres and of the brain. Death from exhaustion in six weeks.

CASE II. Boy of nine, with negative family history. Left nares occluded, cervical glands enlarged, and exophthalmos. It was stated that the boy had been well up to three weeks before. His general condition was so bad that operation was considered inadvisable.

During the congress the following papers were read by title: "Some Thoughts about the Prophylaxis of Nasal Catarrh," by Carl Seiler, M.D., Philadelphia; "A Case of Myxœdema of the Throat," by J. W. Farrow, M.D., Boston; "Tracheal Stenosis," by Samuel Johnston, M.D., Baltimore; "The Treatment of the Early Stage of Diphtheria," by S. H. Chapman, M.D., New Haven; "Erysipelas of the Air Passages," by Wm. Porter, M.D., St. Louis; "Some Observations on Laryngeal Tuberculosis," by S. O. Vander Poel, New York; "Reflex Epilepsy from Lymphoid Disease of the Pharyngeal Vault," by U. G. Hitchcock, M.D., New York.

At the executive session the following were admitted to active fellowship: Dr. G. V. Woolen, Indianapolis; Dr. Emil Mayer, New York; Dr. Ward, Pittsburg; Dr. T. Melville Hardy, Chicago; Dr. W. F. Chappell, New York.

Election of Officers for the ensuing year resulted as follows: *President*, Dr. C. H. Knight, New York; *First Vice-President*, Dr. T. Morris Murray, Washington; *Second Vice-President*, Dr. D. N. Rankin, Alleghany; *Secretary and Treasurer*, Dr. H. L. Swain, New Haven; *Librarian*, Dr. J. H. Bryan, Washington.

The next congress will be held at Washington in connection with the triennial meeting of the Association of American Physicians.

Eczema of the External Auditory Canal.—DR. HERMET (*Annales Oph.*, October, 1895) considers nitrate of silver the best agent to employ. After first cleansing the parts by means of boiled water, soak cotton in a solution of one to ten, introduce into canal, and leave it there for twenty-four hours.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

DR. FOWLER'S GRIEVANCE IN PARLIAMENT—MEASLES—LONDON UNIVERSITY ELECTION—ST. ANDREW'S AND DUNDEE—CREOLIN—HOSPITAL FESTIVALS—SMALL-POX—CAVENDISH LECTURE.

LONDON, June 26, 1896.

SIR W. FOSTER brought forward Surgeon-Captain Fowler's case in the House of Commons, in accordance with the notice mentioned in my last. Several other speakers condemned the abuse of power which had worked such injustice, but the authorities pleaded that a technical breach of military discipline had been committed by the medical officer, who had failed to conform to the regulations. This defence was accepted by the house, and so far justice is still refused. But what a defence in face of the repeated declarations of high officers that the doctors are only "civilians." And this defence is set up for dismissing a surgeon against whom no charge of incapacity is made, and that at a time when the authorities are at their wits' end to find eligible candidates for the army medical service!

You will remember that the only omission of duty charged against Dr. Fowler was that he did not report misconduct which he had reprovved, because military officers, his seniors, were present, and they were the parties to make the report, according to the "Queen's Regulations." Nevertheless, a scape-goat was wanted, and who so helpless as the doctor?

"Murder by Measles" is the rather sensational title of an article in the *Nineteenth Century*, by Drs. Waldo and Walsh. The authors point out that there is a large mortality from this disease, especially in poor districts. Indeed, they estimate the case mortality of such a district at about three times that of the richer quarters. They tell us, further, that in 1894 measles killed in London about twice as many persons as fevers and small-pox combined. On these and other figures they put in a plea for the notification and isolation of measles. Assuming "the wisdom and necessity" of such preventive measures in other specific fevers, they pronounce it illogical to exclude measles with its greater mortality. They consider it a mystery why it should be thought right to attempt to control diphtheria, while measles and whooping-cough are left free. And yet they admit that the cost of isolating cases of measles must be enormous, though they regard that as a sort of national insurance. But it is not the cost alone that has caused ardent notificationists to recoil before the proposal to extend this measure to measles. Notification without isolation would be of no avail, but with the present pressure on our hospitals this looks impossible. Drs. Waldo and Walsh give us no estimate of the "ample hospital accommodation" that would be necessary to isolate the enormous numbers of cases of measles. Nor do they indicate how the popular opinion of the unimportance of this disease is to be changed to such a conviction of its deadliness as to support the advocates of notification and isolation.

Convocation of the London University met on Tuesday, when the election of a representative of the graduates on the senate took place. A list of three persons, to be submitted to Her Majesty for selection of a fellow, was duly proposed, viz., Mr. Rivington, Sir J. Lister, and Mr. R. M. Stephenson. The advocates of transforming the university into a teaching body worked for Sir J. Lister, and are disappointed at

the result, for he received only eight hundred and forty-six votes against nine hundred and sixty-three cast for Mr. Rivington, who, although a well-known medical reformer, desires the university to remain as it is. An attempt was made to make the great reputation of Sir J. Lister subservient to his party, but it must be remembered that Mr. Rivington is a distinguished graduate and also a teacher of great experience. It is not improbable that the result will encourage the government to prolong the *status quo*.

The Dundee College, which was to be incorporated with the University of St. Andrews, has not been able to secure the terms which it desired, and for some time past the public has been made acquainted with the differences between the two bodies. The new college at Dundee seems to plume itself on its modern foundation. The ancient university has no notion of sinking its history and privileges in a mere college of to-day. The university authorities are willing to grant Dundee College affiliation or incorporation on such terms as a college might expect from its university, and, while wishing success to the college, regrets the bitter attacks which it has made on St. Andrews. The truth seems to be that the college at Dundee wants to finger the funds of the university, to which it fancies itself the heir, and is longing to walk into its inheritance. But the end is not yet, and the venerable university may outlive the upstart college. Litigation has been carried on between the two, and will probably be continued.

Creolin has been extensively exploited as a non-poisonous disinfectant, but its absolute safety must not be too confidently relied upon in face of the results of an investigation made at the Veterinary College. In consequence of the effect of a lotion of one in twenty on some valuable ferrets, and of a stronger lotion on a dog, other dogs and cats were experimented on with the application, always with toxic effects and often fatal. Professor Hobday concludes that creolin is a narcotic and irritant poison to dogs and cats, and especially when applied over a considerable area of the body, and its effect is more rapid when diluted with water than when used pure or in the form of an ointment. It is not so easily absorbed from small wounds as from a large area of skin. It would seem, therefore, that more care in its use is desirable than has been previously considered necessary.

The Princess of Wales visited St. Mary's Hospital on Tuesday, and spent about an hour and a half in the wards, speaking a kindly word to each patient. Like other hospitals, St. Mary's is in want of funds, but it enjoys royal patronage. For the memorial Clarence wing £4,700 was raised at the annual dinner last week.

A bazaar on behalf of the Northeastern Hospital for Children was opened on Tuesday by the Duchess of Connaught, who was accompanied by the duke. The object is to pay off the debt, which amounts to £3,000. The present income is £500 short of the requirements of the hospital, which is located in a poor district. Purses were presented to the duchess, containing between £600 and £700, and the bazaar continued open on Wednesday and Thursday.

The annual dinner of the Metropolitan Hospital took place on Tuesday, when £2,762 was announced as the result. This hospital is in much need of help. It contains one hundred and sixty beds, but the treasurer says only sixty-six could be used, for want of funds. It is situated in a densely populated and poor neighborhood, and has separate wards for Jewish patients. It has, therefore, an extra claim on the rich members of the Jewish community.

Gloucester seems to have learned the lesson of the epidemic. It is estimated that when the outbreak began there were nine thousand unvaccinated children

in the city. Of these more than eighty-six hundred have been vaccinated, but Dr. Bond and his staff will not relax their efforts while one child remains unprotected. They have had a hard time, and, I hear, have inspected some nine thousand houses. Some other places, warned by the calamity of Gloucester, are putting their houses in order; for the neglect of vaccination has been very widespread. In London there are districts where the authorities have been growing more and more remiss. Hackney and Islington are among these, and are being hauled over the coals. In the latter an outbreak of small-pox has already begun.

The Cavendish lecture was this year delivered by Mr. Bryant, who devoted it to "Vaccination and its Discoverer." It may therefore be regarded as one part of our celebration of the Jenner centenary.

OUR BERLIN LETTER.

(From our Special Correspondent.)

OÖPHORIN TABLETS FOR THE MENOPAUSE—THE MICRO-ORGANISM OF CEREBRO-SPINAL MENINGITIS—IMPROVED INSTRUMENT FOR AUSCULTATION—LOCALIZING INTERNAL ORGANS.

June 20, 1896.

CONSIDERABLE interest is manifested in the recent experiments of Professor Landau, in regard to the alleged efficacy of ovarian extract in overcoming the varied and distressing symptoms attending the menopause. The distinguished observer gives his reasons for the method on the assumption that the phenomena of the climacteric is based upon a loss of power in the ovaries, and in order to balance such a deficiency that ovarian extract is indicated. He began by giving the minced ovaries of freshly slaughtered animals, but finding them unpalatable for the patients, he succeeded in obtaining an extract which he now administers in tablet form. Each tablet contains 0.5 gram of the extract, and three or four are given thrice daily until an hundred or more are taken, after which, if no success is obtained, the treatment is suspended. He claims to have cured twenty-four patients of the twenty-seven treated. No secondary symptoms have been reported in contraindication of the treatment.

Professor Heubner recently reported, in the *Verein für Innere Medicin*, that he had succeeded in isolating a new germ, which he obtained by the puncture of the spinal column by Quincke's method in living cases of epidemic cerebro-spinal meningitis. Heubner is the first one who has succeeded in demonstrating this coccus during life. This organism is called a "meningococcus," and is identical with the gonococcus. It has the same form and lies intracellular. Sometimes it assumes the diplococcus form, and other times tetraginous form. There is a very striking difference in growth which characterizes this meningococcus from that of the diplococcus of Fränkel, namely, that cultures made from meningococcus grow very rapidly, whereas those made from diplococcus grow very slowly and after a time lose their virulence. Thus far experiments to prove the positive disease by inoculating animals have not been successful. Heubner succeeded, however, in reproducing this disease in animals by inoculating them in the spinal region with a pure culture of this meningococcus. Former experiments of Jäger and Weichselbaum were unsuccessful because the proper animals were not selected. Mice are not susceptible to this poison, while horses, sheep, and goats are. Heubner was able to cause the disease by inoculation into the spinal cord in two goats. He lays much stress upon the demonstration of the presence of the meningococcus for differential diagnosis.

Dr. Schwalbe has perfected the improved instru-

ment for auscultation, the "phonendoscope," which the Italian professor, Bianchi, invented. Schwalbe reported very good results from its use. It consists of three parts—a resonance box (of metal), two rubber tubes for the ears, and a disc which can be placed against the box. This instrument conducts the sound of the organs to the ear, and can partially replace percussion. It produces by percussion different notes, according to the organ on which it is placed. The inventor claims to be able to distinguish even different lobes of the lung. According to Schwalbe's experience, one can hear better with the "phonendoscope" than with the unaided ear. It can be employed on parts of the body difficult of access, and eliminates extraneous and artificial sounds. It is specially good for physicians who are hard of hearing.

Professor Grummach has just published another method for localizing the internal organs. He has experimented with it, together with Dr. René de Bois-Reymond. They illuminated the person on whom the experiment was made with extraordinarily strong Roentgen rays, and were able to see the contours of the organs distinctly on a fluorescent screen placed behind the patient. The laryngeal cartilages, as well as the bodies of the vertebrae and the ribs, were to be seen distinctly as dark shadows. The movements of the diaphragm were clearly demonstrated. The normal movements of this muscle were from five to six centimetres, but in pathological cases only 1.5 centimetres. The experimenters claim to show the ascending aorta, the heart, and the stomach as shadows. In one case of arterial sclerosis the arteries of the arm showed fine dark lines by the illumination. They also claim to have seen the sclerosis of the coronary arteries of the heart. Further, they were able to demonstrate old calcified centres in the lungs.

GERMS AND SERUMS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: After reading the articles in your excellent journal in reference to antitoxin, I cannot refrain from writing you a few lines about germs and serums in general.

When will the medical profession learn that they are being made dupes of by some of the chemical manufacturing companies? These companies discover (?) some great drug or cure. Now, how do they set about to get rich from it? The answer is easy. Some physician of national repute and high-sounding title is sought. He is informed that the very moon revolves about his magnificent reputation and name; in other words, that he is the great medical mogul. They inform him of the wonderful remedy, supply him with some, give him to understand that it will be worth his while to write a scientific article for print about it. What does he do? Tries it in a few cases, writes a long, learned discourse, and gives it up to the company. What do they do? Print his learned article and strew it broadcast over the land. No one dares doubt the wonderful virtues of the remedy, for does not the recommendation come from the great So-and-So?

No one wants to be outdone, so the lesser lights rush into print—everybody goes wild. After a time some doubting Thomas finds nerve and gall enough to call a halt, and in about the length of time it would take the midday July sun to lick up a frost the remedy is a dead cock in the pit. The theory is exploded, but the company has grown rich.

Understand, I do not say all chemical companies are working the profession for what can be gotten out of it, because we are under a thousand obligations to many of them for the standard and reliable preparations they have put on the market.

What of antitoxin? Time will demonstrate, as it has almost done already, that it is a delusion and a snare. If so, you say, how are we to account for the reports of cures made by the leading men in the profession? Here let me say we are only human—big guns, little guns, and all. Enthusiasm carries them off their feet. Everything must bend to the theory; if we look through blue glasses we see blue.

I know of a man with a national reputation who secured a little vial, at great cost and trouble, of a new fad. He held it up before a class and said: "Behold! the science of a thousand years, concentrated in this vial!" The fact of the matter was that he could not have told what was in the vial to "save his immortal essence."

I doubt the efficacy of antitoxin upon two grounds: First, mistaken diagnosis and slight attacks; second, unreliability of figures.

As to the first reason—too many cases are diagnosed diphtheria which are not diphtheria. But, you say, the culture and test will settle it. I say no. We are overenthusiastic over germs and germ theories. The pendulum has swung too far and must come back. Time will prove that we have been too positive about disease germs. Stick a pin there.

Many and many a case of follicular tonsillitis has been called diphtheria, and a wonderful cure reported, and perhaps the physician was sincere in his diagnosis. Beware of the diagnostic powers of a man who reports anywhere from fifty to a hundred consecutive cases of diphtheria without the loss of a single one, antitoxin or no antitoxin.

The greatest medical man in New York or Paris is just as apt to make a wrong diagnosis as a doctor not known outside of his little country village. And with all due respect I say that in many, many cases, were we to judge of the true success of the two physicians by the bona-fide cures made and real good done, the cross-roads man would carry off the palm. Cartloads of men with national reputations are dismal failures in actual practice. Theory is one thing and practice another.

As to the second reason—difference in severity of epidemic, location, care, etc., leads to unreliability of figures. Another reason is that when we are dealing with the human organism we are dealing with a compound, complex, complicated affair. So that if we give a remedy and the patient gets well, what definite reason have we for assuming the patient would have not recovered without medicine?

LINCOLN PHILLIPS, M.D.

HARTWELL, O.

MEASUREMENTS OF THE APPENDIX.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Some one has advised us to give the appendix vermiformis a rest; but, if you, Mr. Editor, will permit, I should like to give the measurements of the appendix as I have found them in some post-mortem examinations made.

In one hundred and fifty cases I have found the length of the appendix to vary from two and a half to nine and three-quarter inches. Only two came above the general measurement—one six and a half, and the other, the longest I have been able to find any record of, nine and three-quarter inches. Both of these extra long appendices were found in males; the canal communicated freely with the cæcum; they were almost free, having only a short mesentery, contained some hardened faecal matter, otherwise were in an apparently healthy condition.

C. J. RINGNELL, M.D.

MINNEAPOLIS, MINN., June 12, 1896.

DOES THE APPENDIX DEMAND SURGICAL REST?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: With due deference to Drs. Morris and Wyeth, whose surgical skill and other attainments are the pride of our common profession, I must submit that they do not, in a measure, apprehend the situation, and they fail to rise to the exigencies of the occasion. The question is not whether the treatment given appendicitis by Drs. Morris, Deaver, Wyeth, McBurney, and others is the best treatment in their, or equally skilful, hands. This was long ago demonstrated, and there can be no question but that in the hands of the surgical expert the mortality is practically *nil*.

Nor would there be question if surgical experts were easily procurable. But, as a fact, appendicitis is common, expert surgical skill is extremely rare, and these few surgical experts are not so self-sacrificing as to respond to telegrams unmindful of the financial responsibility of patients and physicians.

The practical question for myself as a general practitioner, a large part of whose practice is surgical, is, what percentage of appendicitis cases ought I to submit to the knife?

In the solution I ask aid from the profession, and the statistics of Drs. Fenger, MacArtney, and others are valuable to me, if true, while the statistics of Drs. Morris, Deaver, *et al.*, as surgical experts deriving their data from consultation practice, are practically of no value at all.

To refer me to statistics of ninety-eight per cent. of recoveries at the hands of surgical experts, not surgical operators, when I invite aid, is to give me a stone when I ask for bread. The question whether eighty-five patients out of one hundred 'die under conservative management, or whether the mortality in general of appendicitis is only about five per cent.,' is a most important one, as is also the question whether relapse in cases surviving medical treatment is common or otherwise. To such of us as have "sweat blood" in determining for or against operation in certain cases, it is important that these questions be discussed without overestimating the tendency toward recovery on one hand or offering the expedients of the surgical prestidigitator on the other. The opinions of Senn, Fenger, Keen, Lamphear, and others counselling conservatism give us moral support in management of very many cases by medical aid alone. If we listen to the protestations of another school, represented by Morris in the East and Murphy in the West, we shall of necessity operate in the great majority of cases. In the aggregate will it be for good or ill? When Dr. Morris asks: "Why is Dr. Greene willing to have nine per cent. of appendicitis cases die under medical treatment?" he is manifestly unfair in his presentation of the question, inasmuch as he implies that more might be saved by general adoption of surgical practice. This is simply begging the question at issue. The general practitioner bases his practice on:

1st. The assertions of observers like Fitz, Hektoen, and Taft, who assert that thirty-five per cent. of all dead bodies show more or less evidence of appendicitis. So far as I am aware this is not disputed, and must of necessity indicate the inherent tendency of the disease toward recovery.

2d. The expressed opinion of many surgical operators of great experience who are recognized by the general profession as writers and teachers of authority. These men may or may not equal the surgical expert in certain technique, but it is to the consensus of their opinion that the general practitioner must turn for moral support, particularly in medico-legal cases.

¹ Wyeth: MEDICAL RECORD, May 9, 1896.

² Fenger: American Journal of Obstetrics, August, 1893.

3d. The almost universal testimony of most intelligent general practitioners in different sections of our country that a very large proportion of appendicitis patients get permanently well under medical treatment.

Under such circumstances I believe the general practitioner can fairly demand of the surgical expert that the latter give practical recognition of this well-nigh universal testimony, and can serve notice on him that he has no moral right to promulgate rules for the guidance of the general practitioner based on experience that leads him to conclude that eighty-five per cent. die under conservative management.

We general practitioners, who have devoted time and money to learn from them in post-graduate work how to diagnose and surgically treat appendicitis, know that the mortality rate is not so high and that their statistics are not drawn from cases as they occur to the rank and file of the profession.

Nor does it avail to insinuate unrecognized cases under the head of peritonitis, obstruction of the bowels, or typhoid fever, when the competent practitioner recognizes that any obscure abdominal inflammation may prove to be appendicular and when cases of supposed intestinal obstruction or even of acute gastritis threatening death demand and receive surgical interference in order to establish a diagnosis.

What we contend for is that the radical position presupposes moral cowardice or ignorance on the part of the general practitioner, when the fact is that he can give as much reason "for the faith within him" in his particular environment as Dr. Morris can in his.

To step from a carriage to the splendid appointments of a modern operating-room is one thing. To travel before daylight ten miles through mud and rain; to be confronted with unsuspected appendicitis that has demanded operation for days; to personally send messages over warring telephone lines, messages that must be repeated from one to the other; to secure under these circumstances necessary assistants, but with instruments and dressings hastily procured; and finally to operate successfully after 3 P.M. on a dark and rainy day in a country farmhouse is quite a different picture. As for myself, I have experienced both.

Would the gentleman demand ninety-eight, or even ninety-one per cent. of recoveries under these untoward circumstances?

Dr. Morris alleges that he "arouses the ire of fellow-surgeons" and "the enmity of general practitioners." This is to be deplored, as it is not a question of feeling but of fact. Dr. Morris' standing in the profession must disarm any suspicion that he had any feeling toward Dr. MacArtney's statistics, but in our section it has been somewhat the fashion that if any conservative man dared lift his voice he has been "jumped on" by surgeons who were making abdominal sections even upon, in one alleged case, typhoid fever, and whose zeal for operation, in my opinion, is stimulated by the opinions of radical men.

It has been repeatedly urged in the past that we had no ground for argument in the face of statistics and opinions of men like Dr. Morris and others. As stated in the beginning, what is the best treatment in the hands of the surgical expert has been demonstrated. What is the best treatment in the hands of the general practitioner cannot be determined on that line at all. I believe the solution is at hand when the general practitioner begins to gather statistics, lift his voice, and demand a hearing.

J. H. GREENE, M.D.

Dubuque, Iowa, June 13, 1896.

Asthma.—Chloride of methyl spray upon the back, up and down the spine especially, it is said will cut short an attack.

A BAD HABIT OF SOME SMOKERS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your editorial on "Anti-Cigarette Leagues" touches upon a subject not only of great public interest, but one that is ill understood by a majority of the laity. The main facts presented, will not, I think, be controverted by thinking men. There is one most important point, however, which has been overlooked in summing up the evils of cigarette smoking, namely, deep inhalation of the smoke. Inveterate cigarette smokers are invariably addicted to smoke inhalation. Granting that the ill effects are due to the absorption of nicotine and other noxious material by the mucous membranes, it will be conceded that the amount absorbed by the chronic smoke breather will be many times that taken up by one who smokes a cigarette as he would a cigar. Cigar smokers are not smoke breathers. It is, therefore, not only the short smoke offered by the cigarette, but also the pernicious habit of smoke inhalation, wherein lie the evil and danger to our boys and young men.

FRANK P. PRATT, M.D.

JACKSON, MICH.

SPECIALISM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: To the doctor who reads his medical journals regularly, nothing is more entertaining than the occasional rows which occur between physicians on the one hand and specialists on the other. The present wrangle in the *MEDICAL RECORD* between the general practitioner and the appendicitis operator is a thing of beauty.

I plead guilty to the offence of being merely a common every-day general practitioner, nor do I blush at the admission. I am this by choice. I believe I can be a more useful man, and, generally speaking, a more broad-minded man, as I am than by becoming a specialist. So long as human nature shall be what it is, so long will it be hardly possible for a man to devote himself exclusively to one thing without losing more or less of his general view. Every thoughtful doctor will see the necessity of making allowances for this tendency in our nature and of excusing the poor specialist with his limitations for many of his airs of importance. We must do this, because specialists when watched closely by the general practitioner are sometimes useful, and when carefully controlled and restrained undoubtedly do good in certain cases. Furthermore, by hammering at the same thing all the time, they evolve a fact now and then which may be of use in building up the science of medicine as a whole.

But when one of these individuals gets to that point of folly and impertinence that he, so to speak, bursts, and rises on his hind legs to inform the great medical profession that every man who does not treat his patients according to his peculiar formula or theory is incompetent or unscrupulous, it is time for the profession to call such a ridiculous person down and sit on him heavily. It is time for them to bring his attention to the fact which he must have forgotten, that his specialty, no matter how important, is only a side show in the practice of medicine, and that he, no matter how brilliant he may be, is only one of the agile tumblers in that side show.

No, sir! The general practitioner has during the last few years been fooled too often by specialists great and small to be thrown off his guard to-day by every utterance these one-ideal people see fit to give out. He cannot do his duty by his patients unless he takes a firm stand and uses his own judgment and experience in passing upon the jarring and often utterly

unreasonable and contradictory statements with which the journals teem. A specialist is like a man in the theatre with an opera glass at his eye. He sees with unusual clearness the actor on whom his glass is turned, but he sees little else. The rest of the stage he cannot see, and as for the great audience about him, he is for the time being hardly aware of its existence. But all the same he is merely a unit in the multitude, any other unit of which may be as good and as intelligent as himself.

The question of "fat fees" has been brought up by both sides in your recent communications, and therefore I claim permission to allude to it. My experience is that specialists who have seen patients of mine do not usually charge more than a fair sum for their services. On the other hand, I am sorry to say that a specialist may be a very mean and sordid man. I have seen it possible for such a one to send an unrighteous bill to a patient, and, when a polite and proper protest was made, to assume an offensive, menacing attitude, and finally to get down to the level of a greedy pawnbroker.

To come to the question of appendicitis: I have been practising sixteen years and have seen some cases. Not being a specialist, I have not seen anywhere from fifty to five hundred cases in the last year, but in sixteen years I have seen some and known of others. I wish to testify here earnestly that every case I have seen which was not operated on got completely well. I cannot say the same of those which were operated on. Not one of these patients who recovered has had a recurrence. One of these was a lady who was pregnant between five and six months, about three years ago. She got well, and passed through her confinement safely at the proper time. She has had no trouble since and is to-day a well woman. Of course it is in order for some one to say that these were not cases of appendicitis, but such an one will talk in vain, because I know they were, and tell the precise truth, statistics and specialists to the contrary, notwithstanding.

It is the duty of every practitioner to treat every case of appendicitis with a view to save his patient the expense and danger of a surgical operation. Surgeons may prate as they please about the freedom from danger in opening the abdomen, but it is a grave and serious procedure; I have a strong impression that no surgeon would look upon the matter lightly if there arose the question of opening his own abdomen. And even if he has operated successfully on twenty or thirty consecutive cases, he can give no guarantee that the thirty-first will not end fatally. It is this uncertainty hanging over each case which confounds all the statistics, and makes them of no interest or value to the friends or the physician of any patient who may have appendicitis. What shall it profit a woman if her husband is killed by having his belly cut open, if you show her the dry figures which exhibit the previous successes of the surgeon who cut him!

It is the business of the family physician to decide in every case of appendicitis if an operation is necessary. He can decide just as well as the surgeon, because the latter has no means of diagnosis which are not within his reach. And when we reflect that some surgeons are so far gone as to assert that every case of appendicitis should be operated on, the solemn duty of deciding the question for or against operation has got to rest on the shoulders of the general practitioner. Heaven deliver me and mine from that kind of surgeon! He is a reckless and dangerous man.

It is worth while to consider what would happen to the people if the general practitioner did not stand between them and the specialist. By the time the eye-man had clapped on enough glasses to satisfy his longings, and the nose man had gouged out enough

noses, and the throat man had cauterized his fill of throats, and the stomach man had let down his buckets and other paraphernalia into the last stomach he felt called upon to annoy, and the appendicitis hero had satisfied himself that he did not need another appendix, and the circumcision dragon had carried off his allowance of foreskins, and that fearful nondescript, the official surgeon, had humbugged all the human apertures which he longs to get at, and this recent iconoclast who has suddenly jumped into the arena, whose mission in life is to pull the testicles out of old men, shall have got his bag full of the contents of other men's bags—by the time these and many others had exhausted their efforts and become satisfied, there would not be a whole man or woman left in the country. It is becoming more and more the duty of the physician, to the community rather than to himself, to resist the fads which are more abundant in the medical field to-day than ever they were before.

We must have specialists, and the rank and file of the profession will be ever glad to learn any facts they may discover whenever they can agree among themselves for a reasonable time which are their facts and which are their theories. Furthermore, we shall render proper respect to every man who respects us in return and who respects himself; but the day is not here, nor will it ever come, when the general practitioner will consent for a moment to be pushed into the attitude of a schoolboy, while the specialist stands over him with the awful airs of a schoolmaster. All honor to the large-minded man who gives freely of his discoveries to his fellow physicians with the modesty and dignity which marks the true man of science as well as the true gentleman. We all know that kind of man when we see him, and recognize his value. We also know the other kind of man—the little chap with a swelled head. We would suggest to him that he go into the woods and commune with himself. After a while it may dawn upon him that he is only a man after all, and that he may not be a very big one.

W. J. SHREWSBURY, M.D.

BROOKLYN.

Pellotine.—Tolly presented a communication to a Berlin medical society concerning pellotine, a new hypnotic, which is not, like most of our modern remedies, a synthetic product, but is an alkaloid of a cactus-like plant, the *Anhalonium Williamsii*, introduced by Hefter. The natives of India, he said, had long known of the virtues of this plant. The first experiments on animals had seemed to indicate that its action was somewhat similar to that of strychnine, but experiments on the human subject, on the discoverer Hefter himself, demonstrated that pellotine is an hypnotic of the first order. Given in doses of one-third to one grain, it caused, in most of the cases observed by Tolly, a sleep of about four hours' duration, inducing at the same time in almost every instance a slowing of the pulse. According to Tolly's experience, it acts well in the pains of locomotor ataxia, in neuritis, nervous excitement, alcoholic delirium, etc. The only by-effects noted were tinnitus, a sensation of heat in the head, and vertigo. The speaker thought the remedy was worthy of a trial, a change in hypnotic remedies being in many cases of absolute necessity.

Ichthyol in Burns.—This drug is efficacious in treatment of burns of the first and second degrees. It alleviates pain, reduces œdema, and promotes healing. It is used dry, diluted with zinc oxide or bismuth, the powder being spread evenly over the surface; in ointment (ten to thirty per cent.); or as a combination of these two methods.

New Instruments.

A NEW SPECTACLE LENS—A COMPOUND ACHROMATIC PERISCOPE.

By F. PARK LEWIS, M.D.,

BUFFALO, N. Y.

With the more general recognition of the importance of refractive errors in their effects not only upon the eyes, but often upon the general nervous system, has come increased nicety in determining the focal correction, the proper position of the lenses before the eyes,

A. 1, Convex flint-glass cylinder; 2, convex crown-glass meniscus.
B. 1, Concave flint-glass cylinder; 2, concave crown-glass meniscus.
C. 1, Sectional view of both crown and flint glass lenses cemented together; 2, plain flint-glass cover (for correcting chromatic aberration); 3, concave or convex crown-glass meniscus.

the right adjustment of the frame, and an endeavor to relieve the eyes in every possible manner of unnecessary or unequal strain. Comparatively little attention, however, has been given to an element of quite as great, and in some instances greater, importance—the construction of the spectacle lens itself. The imperative necessity of a correction of all spherical and chromatic aberrations in the objective glass of the telescope and the microscope has compelled the makers of lenses to employ the highest skill in their construction. The necessity is equally great in the correction of the higher refractive errors; but, with the exception of the spherotoric lens, which, valuable as it is, has not come into general use because of the necessity of special moulds other than those usually employed, there is no compound focal glass by which spherical errors can be eliminated, and none whatever by which a complete spherical and chromatical correction can be secured. In order to meet the requirements of this class of cases, the writer has devised a practical combination, which has proved to be of such practical value that a brief description may not be without interest. Its simplicity and the fact that it can be constructed at a cost not largely in excess of the ordinary compound lenses give it a very general application. The necessity of a lens of this kind was suggested by the difficulty of securing as high visual acuity after the extraction of cataract and in other cases in which lenses of short focus were required as the absolutely clear media would seem to warrant. Aphakial patients were peculiarly annoyed sometimes by the sensation as of a blue haze surrounding every object, even after the most perfect possible correction with a lens had been secured. A suggestion made some time before by Mr. Herbert Spencer, the well-known maker of microscope objectives, that it was possible to secure achromatism in such strong lenses, led the writer to order in the construction of such glasses

a combination made by cementing a flint-glass cylinder of the proper refractive value upon a crown-glass lens having a plano-spherical surface. The result, while far better than that obtained from the ordinary test-case combination, was still unsatisfactory. The construction was therefore devised of a combination lens based upon the following principles: The spherical surface was to be a meniscus, either concave or convex as might be desired, the proximal surface of which, except a circle at the centre of suitable dimensions, was to be ground to a smooth surface. The plain surface of a cylindrical lens which was placed at the proper angle was then to be cemented upon this proximal surface, a narrow vacuum being left between the two lenses. One lens was to be of crown and the other of flint glass, in order that chromatic correction should be obtained. The strong spherical lens being periscopic, spherical aberration was therefore largely eliminated.

While with such a combination the exact values obtained in microscopical objectives would not be secured, the general effects have been so vastly superior to any heretofore employed as to make this lens an exceedingly satisfactory one. While it has been especially useful in cases of aphakial and highly myopic eyes with astigmatism, it has in some instances given relief in moderate degrees of ametropia in which ordinary lenses have not proved comfortable.

In such it has been especially valuable in giving periscopic vision, whereas with the convexity or concavity wholly in one side of the lens—a necessity in a compound glass—its focal imperfections are manifestly so great as to make the correction at best approximate.

It is evident that in such formulæ as the following, chromatic aberration cannot be avoided except by combining glasses of different refractive index, and the spherical correction can be obtained only by the use of a periscope:

$$R. + 11 \text{ D. sph.} = + 175 \text{ D. cyl. ax. } 15^\circ$$

$$L. + 14 \text{ D. sph.} = + 175 \text{ D. cyl. ax. } 15^\circ$$

$$R. - 9 \text{ D. sph.} = - 2 \text{ D. cyl. ax. hor.}$$

$$L. - 10 \text{ D. sph.} = + 125 \text{ D. cyl. ax. } 90^\circ$$

But in actual practice the most complete correction has been obtained in the above and many other combinations, which have at once proven to be simple, relatively inexpensive, and eminently satisfactory.

Front View of Compound Achromatic Periscope.

The lenses are made by the Failing Optical Company, of Buffalo.

Gonorrhœa.—Dr. Shoemaker says the physician should caution patients suffering from gonorrhœa from carrying the finger to the eye before the hands have been thoroughly washed, as virulent ophthalmia is excited by contact with gonorrhœal pus.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 11, 1896:

	Cases.	Deaths.
Tuberculosis.....	95	93
Typhoid fever.....	15	5
Scarlet fever.....	53	6
Cerebro-spinal meningitis.....	5	6
Measles.....	180	10
Diphtheria.....	214	26
Small-pox.....	0	0

The Jenner Centenary in Berlin.—In Berlin, as elsewhere, the Jenner centenary was celebrated on May 14th, commemorating the first vaccination practised one hundred years before. On invitation of the city, several hundred physicians assembled in the great hall of the Rathaus. After an address of welcome by Virchow, who called Jenner one of the greatest benefactors of humanity, Gerhardt delivered the oration, in which he pictured in brilliant colors the life and labors of Jenner. Kruse, a deputy in the Reichstag, also spoke, referring to the antivaccinationists and warning his hearers against an underestimation of the harm they were capable of doing. The city councilman, Dr. Strassmann, delivered the oration in behalf of Berlin. In connection with the celebration was an exhibition of objects relating to vaccination. There were many Jenner portraits and letters, the pioneers of vaccination in Germany were commemorated, and even the antivaccination literature of the century was well represented. The impression made by this celebration was that the storm of the opponents of vaccination was not likely for many years to come to avail much against compulsory vaccination law.

Starving in Heart Disease.—At a recent meeting of the Berlin Medical Society, Dr. Hirschfeld read a paper on the nutrition of patients with heart disease. He took the somewhat startling position, in which, however, he was sustained with the approval of many of his hearers, that patients with heart disease, in the stage of imperfect compensation, should take as little food as possible, not even enough to sustain the body weight. It was formerly the custom to give as much nourishing food as possible, with the idea of strengthening the heart. The speaker maintained, however, that in this way too much work was thrown upon the heart, and that the organ was spared and its muscle strengthened by giving very little food, say about a pint and a half of milk a day. Senator, among others, agreed with the speaker in this view.

Regulatory Glycosuria.—Dr. Gustav Klemperer, in a paper at a recent meeting of the Society for Internal Medicine, opened up a subject of great general interest, namely regulatory glycosuria and renal diabetes, starting from the remarkable fact that in diabetics who have at the same time albumin in the urine the glycosuria ceases as soon as the disease of the kidney has reached the point of cirrhosis. Thus, a patient with typical granular atrophy of the kidney had formerly four per cent. of sugar in the urine. If, then, only healthy renal epithelium excreted sugar and the diseased epithelium did not, the case must have been one of renal diabetes, which Klemperer thought was also demonstrated by the following: First, it is certain that the diabetes produced in animals by phloridzin poisoning is of renal origin,

for the proportion of sugar in the blood of such animals is not increased after extirpation of both kidneys; and, furthermore, when the phloridzin is injected into the renal artery of one side saccharine urine is excreted only from the corresponding kidney. Klemperer has succeeded, as did von Mering, in producing phloridzin glycosuria in man. This occurred independently of the nature of the food, even when this contained no trace of starchy matters and there was no increase in the amount of sugar in the blood. It had, therefore, all the characteristics of renal diabetes. But as this renal diabetes is possible only when the epithelium of the kidney is sound, the speaker was unable to produce phloridzin glycosuria in a number of patients suffering from granular atrophy. But, on the other hand, Klemperer did not look upon the glycosuria, which was often noted after the exhibition of strong diuretics, such as calomel, digitalis, caffeine, and the like, as of renal nature, but regarded it as a regulatory glycosuria. In these cases the organism is ridding itself of a surplus of sugar, for this glycosuria occurs only when there is an increased ingestion of sugar at the same time with the exhibition of the diuretic, and examination shows also that the proportion of sugar in the blood is increased. Klemperer said that the object of his paper was to direct the attention of clinical investigators to the existence of a renal diabetes, in order to determine whether this experimentally produced variety of diabetes is also an actual clinical fact. He had himself observed a case of this nature, but in this instance the renal affection was already in the stage of granular atrophy. The patient excreted regularly, under the most varied dietetic conditions, about 0.35 per cent. of sugar, but the proportion of sugar in the blood was never increased. The speaker believed that the recognition of this form of diabetes was of practical therapeutic significance, since it would have an influence upon the regulation of the diet.

Syringomyelia.—Professor Eulenburg recently reported a very interesting case of syringomyelia to the Berlin Society for Internal Medicine. The disease had appeared in consequence of an injury of the hand. Through inadvertence a small piece of zinc was left in the wound of the hand, and this had resulted in a severe phlegmon. The first symptoms of muscular atrophy appeared soon afterward, first in the arm on the side of the injury. Eulenburg held to the traumatic origin of the affection, but did not believe that the presence of the zinc in the wound was of any etiological significance. The case was one of great importance, in relation to the laws governing accident insurance in Germany.

Medical Philadelphia.—The *Medical and Surgical Reporter* says that it is not, as we had supposed, administering weekly rebukes to its readers in that city for their lack of energy and failure to keep abreast of the times. "Readers of the *Reporter*," it truly says, "are necessarily fully abreast of the times. Even those physicians of Philadelphia who do not regularly read the *Reporter* cannot be said to be far behind the times. The generous support of New York journals indicates that a considerable portion of the Philadelphia profession is, or at least ought to be, as far advanced as is the profession in New York, concerning whose doings it is much better informed than it is of current work at home. However, the *Reporter* has never alleged 'a lack of energy or failure to keep abreast of the times' on the part of the Philadelphia profession as practitioners of medicine. Its comments have been upon the business policy and the fatuous methods of the body medical, the effects upon Philadelphia's reputation, and the derogation of the city's claim as the medical centre of America."

THE ENDOTHELIUM OF THE FREE SURFACE OF THE PERITONEUM.

By BYRON ROBINSON, B.S., M.D.,

CHICAGO,

PROFESSOR OF GYNECOLOGY IN THE POST-GRADUATE SCHOOL.

VALENTINE discovered the peritoneal endothelium. In 1862 Von Recklinghausen discovered that a solution of nitrate of silver produced dark lines between endothelia. In 1865 His introduced the name endothelium for the peritoneum instead of epithelium. Endothelium in general is a nucleated membrane, as the endothelial plates of blood-vessels and lymphatic vessels, and the lining of lymph sinuses. Many capillaries have their wall composed of simply a single layer of endothelium, *i.e.*, flat,

membranous nucleated plates joined edge to edge so as to compose a hollow tube for fluid conduction. Endothelium is derived from the middle germ layer of Pander and Baer. In this article will be discussed that form of endothelium which lines the free surface of the peritoneum. In other words, we will consider the connective-tissue cell which is flat and smooth on one side, for the peritoneal endothelia are only modified connective-tissue cells. The origin of peritoneal endothelia is no doubt due to fluid pressure in lymph spaces and visceral motion independent of the body wall. I mean

by this that the fluid pressure in lymph spaces became so constant and so vigorous that the fine partitions gradually atrophied or became absorbed until the spaces coalesced so much that a lymph space of varying size arose. This enlarged space is lined by what we are terming endothelial plates. Added to this, the viscera adjacent to these developing and coalescing lymph spaces become more and more independent in their movements relative to the body wall. Thus, by increasing development of lymph spaces and by increasing independent motion of viscera and body wall, the great lymph sac—the peritoneal cavity—was formed with its smooth lining endothelial plates. This evolutionary process in producing a monster lymph sac with smooth walls was an act of adaptation of the viscera to their environments. The need of progressive visceral growth and fixation of body wall was motion and this was accomplished by fluid in a

smooth sac. It reduced friction to a minimum and increased motion to a maximum.

By peritoneal endothelia is implied a layer of flattened, smooth cells lining its free surface. The plates of endothelia are so arranged edge to edge that a continuous, non-interrupted membrane is produced. Peritoneal membrane is different from mucous membrane or the membrane which lines glandular cavities. Mucous membranes possess epithelium and arise from hypoblast or ectoderm. The peritoneal membrane, serosa abdominalis, is derived from mesoderm or mesoblast. The naked-eye appearance of normal peritoneal endothelium is that it is shiny and glossy. The eye can distinguish no lines or unevenness on its surface: it is smooth. In color it is grayish-white, pink, or pearly, depending, however, on its vascular condition to some extent. It is transparent and many structures may be observed beneath it. The endothelial layer itself does not change so much in appearance as do the subjacent structures. Fat makes it appear yellow, pigment cells dark, while bile-stained subjacent structures give it a variegated color. In short, its color arises from subserous organs and conditions. Previously diseased endothelia returned to normal may even show a mottled condition.

To the touch the endothelial membrane feels smooth and moist. It is slippery from the viscid condition of its secretions. It is so thin that one could perhaps not distinctly feel less than four or five layers between the finger and thumb. The best method for observing the thin portion of the endothelial layers is to allow it, especially that from the omentum majus and gastro-splenic, to float in a large capsule of water, when the thin, delicate membrane will move about, sometimes almost invisible. On exposure to the atmosphere it quickly becomes dry, wrinkled, and brittle. A brownish color appears to arise when it becomes dry.

The extent of the peritoneal endothelium is not very much less than the extent of the skin. The endothelia, *i.e.*, the connective-tissue cells flattened and smooth on the free surface, are the essential elements of the peritoneum. Without the endothelia the peritoneum is robbed of that element which endows it with physiological properties and is the principal factor in preventing the invasion of disease.

The preparation of the peritoneal endothelium and the interpretation of its appearance under the micro-

FIG. 1.—Drawn from Frog's Cisterna Lymphatica Magna. (Oc. 2, ob. 8 a, Reichert.) The surface directed toward the cisterna is shown. Eight stomata vera are shown; some partially open, others tightly closed. Some of the cells of the stomata vera are marked with nuclei. There are scores of other stomata vera adjacent and distributed similarly. 2, The stomata vera cells showing no nuclei; 3, with two nuclei; 4, with one nucleus; 5, an elongated stoma verum.

FIG. 2.—Drawn from Omentum Majus of New-born Child. It represents what I shall term a giant (6) endothelial cell surrounded by many small irregular ones. This irregularity I think cannot be the result of trauma, as it was handled with precaution. The giant cell is less stained than the adjacent endothelia. The omentum of this newborn is in a state of wild irregularity as to shape, size, and grouping of endothelia. 1, 2, 3, 4, stomata vera; 5, stomata spuria (adjacent in the microscopic field, not here shown, are other smaller giant endothelial cells surrounded by smaller groups); 6, giant cell; 7, common endothelia.

scope are the first steps to a knowledge of structure and function, and it is the second step to make such knowledge of practical benefit to combat peritonitis, the vigilant enemy of mammalian life. The first precaution in preparation for the observation of the peritoneal endothelium is that the membrane be as fresh as possible.

The second is that all possible trauma to the membrane be prevented: manipulating, dragging, and tearing must be avoided. The membrane should be handled only in a fluid medium, and even in the fluid with as little movement as is compatible with results. For the fresh specimen an animal may be killed and the parts of the peritoneum to be examined gently cut out with very sharp scissors

should be allowed to shine on it. The results depend on the strength and time the silver solution remains on the endothelium and the duration and intensity of the sunlight. I have examined specimens two months after mounting in glycerin, which were continually exposed to light and they improved with age. The silver-stained endothelium should remain in distilled water for an hour before it is placed in common water, for the salts in common water interfere with the working of the Ag No. 3 solution. If one wishes to check the effect of the silver solution on the membrane it should be placed in a salt solution, one-half per cent. Any trauma exercised not only is liable to desquamate the endothelium, but it will be liable to disturb the peculiar structures known as stomata vera, as well as the inter-endothelial substance, and, as this last-named material is pliable, semi-fluid, it can also become disarranged.

What does one see on looking at a silver-stained peritoneal endothelial specimen through a microscope? First, he sees irregular dark lines which separate brownish spaces from each other. These dark lines are precipitated albuminate of silver, the inter-endothelial substance being of an albuminous nature. Some have claimed that the dark lines are only precipitated albuminous fluid substance which exists in furrows on the endothelial membrane, for all admit a serous fluid exists on the surface. Some claim that the lines are elastic fibres. Schweigger-Seidel enunciated and defended this view persistently, and as proof said that if the peritoneal endothelium be first washed with diluted glycerin or diluted sugar solution the silver solution will not produce the dark lines. However, Klein positively denies the assertion. He repeats the rinsing of the membrane, and says the silver solution then produces the lines as before. Also, that by rinsing the peritoneal endothelium with water the silver solution will still produce the dark inter-endothelial lines. Hence this is sufficient proof that the dark inter-endothelial lines are not on the surface at all, but in the semi-fluid inter-endothelial substance between the plates. I can say that I have repeatedly watched the effect of the silver salts on the inter-endothelial lines, from just perceptible dark lines until a week later, when the lines have thickened in breadth, and also to some extent shown some connection with the substance on the endothelial plate: the endothelial plate will gradually brown deeper and deeper from the circumference of the plate, *i.e.*, from the inter-endothelial line toward the nucleus of the cell plate. But the dark, irregular, inter-endothelial lines appear first. Now, in many endothelia the nucleus remains an oval or round clear space, *i.e.*, the silver solution did not brown it, but the circumference of the nucleus is intensely brown. The only reasonable explanation I can offer for this phenomenon is that the nucleus is higher than the rest of the cell and therefore the silver solution flows away toward the edge of the plate; consequently, we shall assume that the dark, irregular endothelial lines are precipitates of albuminate of silver and therefore that they represent the outline of the peritoneal endothelial plates. There is a wise provi-

FIG. 3.—A, Drawn from Adult Human Omentum Majus. (Oc. 4, ob. 3, R.) It shows, 1, a stomata verum surrounded by six cells; 2, a stomata verum; and 3, a very brown spot on the surface of an endothelial cell, perhaps a rift or precipitated debris; 3, free edge of trabecula. Note the irregularity of the endothelial cells over a field of fat globules; doubtless the irregular growing fat globules account for the irregular shape and size of the endothelia.

B, Drawn from an adjacent trabecula (oc. 4, ob. 3, R.) surrounded by six cells. 1, Stomata verum with two long rifts and a round, white spot in it; 2, endothelia quite irregular; 3, free edge of trabecula. Note in both A and B that the inter-endothelial lines extend into the stomata verum and that the granular substance shimmers through.

and examined in serum from the animal's abdominal cavity, or placed in a large capsule of distilled water. Small bits of the membrane can be snipped off, allowed to float on the slide, and then examined in serum, water, or a drop of glycerin applied to the under surface of the cover glass just before it is placed over the specimen. A one-half-per-cent. solution of common salt (NaCl) is an excellent medium. Much knowledge may be gained by the microscopical examinations of such specimens; in fact all the knowledge of peritoneal structure rested on such examinations up to 1860. But I shall base my investigations and interpretation on peritoneal endothelium treated with Ag No. 3 solutions, as Von Recklinghausen taught thirty-five years ago, besides the more modern reagents. The Ag No. 3 solution should be of from one-quarter to one-half per cent., always in distilled water, and should be freshly made every two weeks (two grains of Ag No. 3 to an ounce of distilled water). For example, a rabbit is killed by bleeding or other method. The abdomen is opened with care and a solution of Ag No. 3 is poured over the peritoneum *in situ*, while the animal lies on its back. No viscera or peritoneum should be touched or traumatized before the Ag No. 3 is poured on the peritoneum. The silver solution should remain from two to fifteen minutes. But by experience and knowledge of desired results one soon learns how long to leave the silver solution on and how much sunlight

FIG. 4. Gastro Splenic Omentum of two months' Fetal Pig (oc. 3, ob. 8 A, R.), showing endothelia grouped around stomata vera. 1, Stomata verum which shows a distinct vertical canal lined with granular cells, which stain well with Ag No. 3; 2 is not quite so plain, as some of the guard cells have dropped out. The foetal pig shows the most typical grouping of endothelia of all animals which I have examined. The typical endothelia groups surrounding a stomata verum only occur on germinating tracts. It appears that with age the endothelia become more polygonal.

FIG. 5 is drawn from human omentum over a field of fat globules. The irregularity of its endothelia is doubtless due to the irregular expansion of the fat globules. 1, 1, Stomata vera; 2, 2, endothelia representing centres of endothelial grouping. Several endothelial cells were required to cover one fat globule, and the microscopic focus required readjusting for endothelia on the top of the fat globule and at its base. In this cut irregularity of endothelial contour and variation of focus for uneven surface are noticeable.

sion in this inter-endothelial substance being semi-fluid, in that it accommodates motion and friction to such a degree that the endothelial plate will not be torn. The brownish precipitates on the endothelial plate after the application of silver solution must be of an albuminous nature also. Perhaps it is albuminous fluid lying on the uneven surface of the endothelial plate, of a nature similar to that of the inter-endothelial substance.

In the inter-endothelial substance is the seat of the physiology of the peritoneum. At the common junction of several (three to fourteen) endothelial plates may be observed an oval or round opening known as a stoma. The mouth of this opening takes on a deeper stain than the surrounding endothelial plates and it is lined by granular polyhedral cells. The stomata-vera cells no doubt are young cells and contain more precipitable albumin, and hence are darker than the adjacent endothelia. The opening shows itself to have depth and hence may be termed a vertical canal. The interpretation is that the stomata (stigmata) vera are vertical canals lined by granular polyhedral cells and serve as a communication between the peritoneal cavity and the subperitoneal lymph channels. It seems to me that they regulate serous fluids.

Again, on the single inter-endothelial lines are found black dots, stomata spuria, or pseudo-stomata, which

FIG. 6.—From Human Broad Ligament. Age 39, dead 20 hours. Ag No. 3. (Oc. 4, ob. 4, R.) The drawing represents two stomata vera; 1 is open, 2 is closed. The endothelia are quite small and of a fairly uniform shape. This specimen was taken from the peritoneum where it diverged from the lower surface of the Fallopian tube. In this locality the subserous lines—fibrous and elastic—are very rich in quantity, making it appear that the peritoneum which loosely surrounds the Fallopian tube is quite thick and strong. The germinal endothelia surrounding the stomata vera are intensely brown.

with logwood, we note sharply defined round or oval bodies, which are interpreted as nuclei. Thus, in the technique of preparations of peritoneal endothelia much of the interpretation is dependent upon the kind of reagent employed. I must say that neither the technique of microscopical preparations of peritoneal endothelia nor the interpretations thereof are universally agreed upon. Many claim that the interpretations of what is known as stomata vera rest on a faulty technique.

The shape of the endothelia varies in different animals and is different in the embryo and in the adult. However, generally analogous-shaped endothelia are found in analogous localities. Afonassiew, Muscatello, and others appear to think that the general and original form of an endothelial cell is polygonal. My examinations include man, the cow, sheep, horse, pig, cat, bird, dog, rabbit, frog, and the embryos of pig and man. So far in the examinations I cannot generalize any single form of endothelial cell. It is probable that the polygonal form outnumbers any other single form. Again, the endothelial cells or plates in the embryo are quite different from those in the adult. The frog possesses the largest and most irregular forms of endothelia of any animal I have examined. The horse and cat possess large areas of very uniformly shaped endothelia.

The outlines of the peritoneal endothelia are generally those of curves and straight lines. Occasionally we find sinuous outlines which may resemble the cranial sutures. But sinuous outlines is the chief characteristic of endothelia covering lymph channels. Some endothelia are perfectly round, some show obtuse angles, while others show acute angles. They may be oval, square, spindle-shaped, or present graceful loops and necks, or assume the shape of a rectangle. They may be triangular (pig), pentagonal, or

FIG. 7.—A, New-Born Human Omentum Showing Stomata Vera and Spuria and Very Irregular Shape and Size of Endothelia. 1, Stomata vera, a typical case; 2, 3, 4, other stomata vera; 5, stomata spuria; 6, stomata verum with its granular polyhedral cells; 7, 8, endothelia dropped out.

B, Drawn from a foetal (two months) pig's diaphragm, abdominal side. It shows a typical stomata verum (1) and it represents it distinctly as shimmering through the common endothelia (2 and 3). There is a round black dot in the centre of the stomata vera through which growth process takes place. The endothelia on this foetal pig's diaphragm are much more regular in shape and size than on new-born humans.

FIG. 8.—(b) Pleural Side of Diaphragm. Drawn from pleural surface of three-months-old dog. Ag No. 3. 1, 1, 1, Stomata vera; 2, 2, 2, stomata spuria; 3, 3, 3, nucleus. This, no doubt, covers lymph vessels.

FIG. 9.—(a) Abdominal Side of Diaphragm, Dog's (three months old) diaphragm. Cent. tend. Abdominal side. Ag No. 3. (Oc. 2, ob. 8 a, R.) 7, 7, Membrana limitans, from which the endothelia have been shed; 1, stomata vera; 2, 2, 2, stomata spuria, inter-endothelial stoma.

are interpreted as connective-tissue corpuscles or lymphoid corpuscles. It is supposed that the young connective-tissue corpuscle projects upward between the endothelial plates and becomes stained with the Ag No. 3 solution. Again, in the preparation of peritoneal endothelium with silver salts we notice that portions of the membrane take on a very much denser coloring from the silver than do the adjacent portions. The intensely browned portions with very irregularly sized cells are interpreted as young endothelia or germinating endothelia. We also note in preparing some portions of the endothelium that certain cells are vacuolating, *i.e.*, the endothelia are multiplying to produce lymph channels. If the endothelia are stained

hexagonal. The length may exceed the diameter, perhaps by six times. But the peritoneal endothelia do not vary in size like the endothelia covering lymph channels. In many cases, especially in embryos or new-born, the long, rectangular endothelial plate may assume a bent or curved shape to accommodate blood vessels and trabeculae. A peculiar appearance is lent to the surface of the endothelium by the reception of an acutely pointed angle in the recess of two or more other endothelia. The uniform shape of considerable areas of endothelial surface in some animals produces a beautiful mosaic, which is occasionally only varied by stomata vera and spuria. In other regions the delicate mosaic is relieved of its uniformity, especially

in the omenta, by germination and vacuolation of cells, while streaks of fat globules may come in to vary the scene.

The varied shape of the endothelia found in the adult body I am now fully convinced is an acquired

FIG. 10.—Horse's Gastro-Hepatic Omentum. (Oc. 4, ob. 3.) Drawn with absolute care. 1, One of the nuclei of a granular cell, i.e., the protoplasm has shrunk; 2, granular cell of stomata verum; 3, rift between two endothelia, debris brushed off; 4, half-cells not brushed off; 5, half-cell fallen off; 6, half-cell closed and open (very numerous); 7, a cell around which seven endothelia are grouped intercellularly; 8, rift or precipitate. The drawing is taken from between two tendons and is much lighter in color than the endothelia covering the adjacent tendons. Note the uniform shape and size of endothelia. Large tendinous bundles exist under this endothelium.

condition, and the plate is so incidentally found in one or the other condition. So far as the elastic feature of endothelial plates is concerned it is a well-known clinical fact. The distention accompanying ascites and the sudden contraction of the peritoneal endothelia immediately following the evacuation of the ascitic fluid are sufficient proof. Of course the chief elastic force lies in the subserous elastic fibre. But the endothelial plate must contract very much to readapt itself to its original form. If it did not contract enormously the edges would overlap.

However, we must not allot too much elasticity to the endothelial plate, for the inter-endothelial semi-fluid substance has also no doubt shared in the expansion and actually shared in the contraction.)

(c) The semi-fluid, soft, yieldable inter-endothelial substance allows varieties of shape. This view appears the more reasonable when in all probability ascitic fluid rests on peritoneal inflammatory origin; hence the very œdema alone accompanying peritonitis would expand the inter-endothelial substance. In experiments I note that alcohol and formalin contract the endothelia while water expands them. Again, by observ-

FIG. 11.—Omentum of Horse, perhaps Twelve Years Old. 1, 1, Stomata vera; 2, 2, nuclei; 3, rift in cell edge; 4, stomata-verum cell with two nuclei; 5, stomata vera with two cells, each having a nucleus (note it has nine cells around it); 6, an extension of the stain; 7, stomata-verum, five nuclei in it; 8, a granular cell of stomata 1 (Oc. 4, ob. 3); 9, there are here four stomata vera very granular; 10, rifts between cells; 11, stomata spurium; 12 shows stomata vera indefinitely divided with a nucleus to each cell. This drawing is of epithelia lying adjacent to regions with innumerable stomata vera. It is from the surface of a trabecula. The horse's peritoneal endothelia is characteristic for peculiar irregularity and grouping of endothelia. This endothelium lies in a germinal tract.

ing many specimens occasionally one will be found in which the bent or curved endothelium will spring forward and backward in the waving water, such condition being best observed by elevating the cover glass above the slide sufficiently to allow free fluid currents in various directions. On organs, to which the endothelia are quite fixed, but which expand and contract in a rhythm, the endothelial plates no doubt expand and contract, yet some of its adjustability must be due to the semi-fluid albuminous inter-endothelial substance.

The acquired-shape of the endothelial plates from expansion and contraction of vessels due to emptying and filling I have investigated to a considerable extent. If one of the figures is observed, a typical sample may be seen in a frog's mesentery, in which the endothelia covering the blood-vessels are enormously elongated transversely over the vessel from its emptying and filling. Of course an elastic endothelial plate is like rubber, which, being repeatedly stretched, loses some of its original shape and gradually assumes a shape in accord with the direction of its chief tension. Now the acquired shape of endothelia is not alone due to the emptying and filling of blood and lymph vessels, but the shape of endothelia may be gradually moulded by fixed organs which have a definite movement to go through.

For example, the stomach is fixed at the pylorus and the entrance of the œsophagus through the diaphragm, but the chief portion of the stomach as it empties and fills repeatedly passes, no doubt, through the same motions, and in this manner certain portions of the peritoneal endothelia will acquire a shape peculiar to the direction of the chief force. The same may be said of the emptying and filling bladder. Whatever the factors be, the peritoneal endothelia assume a wonderfully varied shape—a multiform outline. In other words, the major and minor diameters vary in a wide degree.

It may be noticed that on the mesentery and diaphragm of the horse, cat, dog, and other animals, organs which possess a high range of motion, the endothelia are smaller and more uniform than in many other parts. In adult animals the endothelia are subject to a wide range of shape. The shape of the endothelia in embryos and new-born also has a wide range. I have noticed in pig embryos enormous numbers of triangular endothelia and also those having the shape of a cone with a curve for a base. Another element which produces acquired changes in the shape of endothelia of both new-born and adults is the development and disappearance of fat. Fat globules simply collect and expand in a connective-tissue corpuscle, and as the fat globules accumulate and expand the endothelia immediately over them acquire new

FIG. 12.—Gastro-Splenic Omentum of Three-months-old Fetal Pig. This is a typical group of endothelia surrounding two stomata vera. (Oc. 2, ob. 8 a) 1 points to stomata vera with one cell broken away; it is surrounded by eight endothelial plates; 2, 2, nuclei; 3, 3, endothelial plates; 4, stomata spuria; 5, stomata verum surrounded by plates; 6, 6, stomata spuria; 7, inter-endothelial stoma; 8, 3, endothelial plates. This very typical figure is drawn as closely as possible to nature. It illustrates the original arrangement of the endothelia of the peritoneum and I cannot too highly recommend the foetal pig for peritoneal study. Its stomata cannot be mistaken and its vertical lymph canals show appreciable depths.

shapes. The endothelia on the top or summit of the fat globule become much more varied in shape than the endothelia at the base or circumference of the fat globules. I sketched several figures of fields of fat globules to show the very marked variation in the shape of the endothelia covering them. Under histology should be included the shape of the germinating and vacuolating cell, for these are simply renewing the place of dying comrades. It may be stated in general that the germinating or growing cells are of all shapes from polyhedral to polygonal. The granular polyhedral cells lining the vertical lymph channels or composing the stomata vera are one typical set. The innumerable round and oval forms accompanying many tracts of peritoneal germination represent another set. The germinating cell is almost endlessly variable in shape, *i.e.*, outline.

The arrangement of the endothelia is a subject of more significance than its shape, for in the arrangement appears to be the original physiologic indication. It appears to me that the pig embryo shows more definite arrangement in its endothelia than any of the above-mentioned animals. One can note very systematic arrangements of endothelial plates around stomata vera, on the gastro-splenic omentum, and quite

FIG. 13.—From a Young Dog's Kidney. The peritoneum was snipped off with a pair of scissors. (Oc. 2, ob. 8 a, R.) Ag No. 3. Note the grouping of cells. 1 and 2 are two endothelial cells around which eight cells are grouped. The cells are quite uniform. The fibrous and elastic network below the endothelia is very dense. Two endothelial cells are not drawn brown from the Ag No. 3.

symmetrical. In other portions of the pig's peritoneum the triangular shape of some endothelial plates allows a symmetrical mosaic to be produced. The first arrangement of endothelia to which attention may be called is that around stomata vera. The stomata vera are situated at the common junction of from three to fourteen endothelial plates. In the embryo pig there exists the most typical and symmetrical arrangement of endothelia about the stomata. The endothelia assume a cone shape and their sharp points meet in common about the stomata. It would appear that in these embryos the symmetrical arrangement of endothelia about stomata vera was a design of nature to accomplish the purpose of physiology in the peritoneum. I am convinced they are preformed openings, original, anatomic, and physiologic structures for the purpose of holding in definite relation the peritoneal cavity and the subperitoneal lymph channels. The circumferential edges of the stomata vera are lined with granular polyhedral young cells, around which are symmetrically or otherwise placed endothelia. The stomata vera are at the common junction of endothelial plates.

The endothelia tend to group themselves about stomata vera. The number of endothelia composing the group include from three to fourteen cell plates. The best samples of endothelia around stomata I found in the embryo pig, but the frog and other animals also produce good samples.

Again, there is a tendency for the endothelium, espe-

cially in early embryos and even in adults, to arrange themselves in relation to blood-vessels. The elongated shape of the plates is easy to make out, grouped in large numbers along the course of the blood-vessel. Great whorls of long rectangular endothelia, curved to suit the course of the vessel as it lies in a trabecula, may be plainly viewed in embryos and in a less typical condition in adults.

If one examines the centrum tendineum of the diaphragmatic peritoneum under the microscope, long, straight dark and light streaks may be observed. The dark streaks or cords are the tendons of the diaphragm, while the light streaks are the spaces between the tendons. By careful observations of the abdominal diaphragmatic serosa it will become apparent that the endothelia covering the tendinous or dark streaks are of a larger size than those covering the light spaces. Hence the distribution of the endothelia is arranged in two tracts over the diaphragm. The explanation first given to the phenomenon by Ludwig and Schweigger-Seidel was that the endothelia covering the light spaces between the tendon bundles of the diaphragm were over lymph channels. In other words, the lighter inter-tendinous spaces are really long lymph tracts, and as endothelium approaches lymph channels it is known to change its outlines and become more sinuous and smaller. For the purpose of demonstrating the arrangement of the endothelia on the tendinous and inter-tendinous portions of the diaphragmatic abdominal serosa the rabbit is first recommended. So far as the arrangement of the peritoneal endothelia is concerned, it is simply irregular. The irregularly shaped endothelia become arranged so that they wrap themselves around the trabecula, leaving no subserous tissue exposed to the abdominal cavity. I generally found the endothelia more irregular in shape and arrangement on the viscera than on the omenta, diaphragm, and parietes. No doubt this greater irregularity of shape and arrangement on the viscera is due to the greater and wider motion of viscera. The shape and arrangement of endothelia differ in different organs and even in the same organs of the same animal. The wide variation in shape and arrangement of peritoneal endothelia must rest on (a) original or (b) acquired condition. What the primordial arrangement of the endothelia is we are not yet informed, though some think the original shapes of the endothelia are polygonal and others think they are preformed about stomata vera. In primordial arrangement of endothelia it appears to me, judging from my own work, that they are preformed about stomata vera.

As to shape of endothelia it appears probable that they were originally polygonal. The acquired shape and arrangement of endothelia are a matter which rests more on physical forces of a tangible nature. Motion, friction, expansion, and contraction unfold a long evolutionary story in acquired conditions of the endothelia of the free surface of the peritoneum.

After the consideration of the shape and arrangement of the endothelia we will take up the constituents of the inter-endothelial substances, which include three divisions, viz.: (a) the stomata vera, (b) the stomata spuria, and (c) the inter-endothelial substance itself, or rather inter-endothelial space.

The stomata vera are round or oval openings situated at the common junctions of three or more endothelial plates. They were discovered by Von Recklinghausen by injecting milk or other finely divided matter into the peritoneal cavity of animals and

FIG. 14 is drawn from omentum majus of new-born child to show grouping of cells around a stomata vera. 1, 2, 3, Nuclei; 4, granular cells; 5, endothelium. The group is composed of eight cells.

then tracing its absorption through the abdominal serosa by the aid of staining with silver solution. The careful methods of experiments by which Von Recklinghausen arrived at his conclusions in regard to the stomata vera on the diaphragmatic serosa are worthy of the highest admiration. With persistent and indefatigable labor he worked the matter out systematically from beginning to end, the chief part of which may be read in *Virchow's Archiv*. The stomata vera are among the chief structures in the endothelia of the free surface of the peritoneum. They are found distinctly in all the animals enumerated in this paper. In fact no animal was found without numerous stomata vera. The typical locality of the stomata vera are omenta and abdominal serosa of the diaphragm. However, my best specimens generally come from the gastro-splenic omentum. They may be found open or closed. The embryo pig, the rabbit, and the frog furnish in my experience the most typical stomata vera. It appears to me that the stomata vera are the centres or preformed openings around which endothelia group themselves. Of all animals examined the embryo pig on its gastro-splenic omentum furnished the most typical, systematic, and numerous grouping of endothelia about stomata.

FIG. 15.—Young Dog's Gastro-Hepatic Omentum. (Oc. 4, ob. 3, R.) A group of ten cells surrounding a stomata verum with two nuclei. 1, Nucleus of stomata verum; 2, stomata-vera cell or guard cell; 3, one of the group of endothelia; 5, rift between endothelial plates.

If one examines the stomata vera situated at the common junction of several cells, with a high power after staining with Ag No. 3 solution, there can be observed at their mouths which open on the free surface of the peritoneal endothelium small, reddish granules possessing a nucleus. These small masses are much darker red than the surrounding area and of a distinctly granular character and they may present a granular polyhedral shape with nuclei. They are in all probability young germinating cells lining the surface of the canal known as the stomata verum. The silver solution intensifies their color. After considerable time spent on examinations of many scores of specimens, I am convinced that the stomata vera are canals lined with granular polyhedral nucleated cells. The stomata vera are not only mouths, but canals of more or less perceptible length. In short they are vertical canals lined with granular cells passing through a definite distance and structures of the peritoneum. In the embryo pig the stomata vera may appear like the interior of a long, thick cylinder or like the cavity of a well lined with stone. The stones may represent the granular cells. In the diaphragm of the rabbit I could find some of the stomata-vera canals passing obliquely from the peritoneal endothelia in the subserous lymph channels showing a distinct length. If trauma be inflicted on the specimen examined, one may frequently observe a part of the granular polyhedral cells which line the vertical canal broken away, adherent in a beaded line, and floating about in the glycerin under the cover glass. It shows distinctly where it was previously situated and waves about as a still intact membrane. Again, trauma which may be due to the Ag No. 3 solution will produce a cleft between the lining membrane of the vertical canal or stomata verum and the smooth mouth made by the common junction of the endothelial plates. The cleft may be empty or filled with granular debris. The cleft or rift between the granular lining cells of the stomata verum and smooth circumference produced by the common junction of the several endothelial plates may be compared to the separation of the mucous membrane of the ureter from its outer wall produced by passing a sound. The loose mucosa of the stomach may also be

compared to this result of traumatic separation. It is easy to separate the stomachic mucosa from the outer wall. It may be that the granular lining membrane of the vertical stomata vera contracts by the application of Ag No. 3 solution. The vertical canals of which stomata vera are the mouths are not always perpendicular to the peritoneal surface. They pass from the endothelia of the free peritoneal surface to the subperitoneal lymph channels in an oblique direction. The specimens obtained from a rabbit's diaphragm after injecting a carmine solution into its abdomen

FIG. 16.—From Woman of 30 Delivered Twelve Hours, who Died of Eclampsia and Acute Peritonitis. Bit off a broad band reaching from uterus to rectum. This sketch was drawn with Ag No. 3. (Oc. 4, ob. 3, R.) Stoma verum is perhaps a vacuolated cell, as is also 3; 4, shed endothelia (the whole patch is germinating and very brown); 5, nucleus. It shows that on peritoneal bands new endothelia frequently spring up, i.e., connective-tissue corpuscles flatten out and assume endothelial functions. The only difference that I have so far noted between endothelia found on an old inflammatory peritoneal band and common original peritoneal endothelia is that the new endothelia found on the old peritoneal band of exudate are generally smaller.

FIG. 17.—Sheep's Omentum Majus. (Oc. 4, ob. 3, R.) Some of the granular cells contain nuclei. The figure represents two stomata vera surrounded by somewhat irregular, coarse, granular endothelia. Stoma verum 1 has nine granular cells around its open mouth, while 2 has four granular cells around its closed mouth. The granular cells 3, 4, and 5 contain double nuclei showing rapid growth or division. Some stomata vera show an elongated mouth closed like the human lips, and may have a dozen granular cells lining the circumference of the mouth. 6 and 7 are common surface endothelia and 8 is a nucleus of same.

fourteen hours before death would indicate that many of the stomata of the lymph channels lie immediately beneath an endothelial cell of the peritoneal surface, and it would appear that occasionally the endothelial cells show marked symptoms of a very granular nature and a semi-fluid character. It is difficult and almost impossible to assert whether the granular condition of the peritoneal endothelium immediately over the stomata of the lymph endothelia is original or acquired. But when a stomata verum of the peritoneal endothelia is found directly over a stomata verum of the endothelia covering lymph channels the picture changes to something more definite. By slowly turning the fine adjustment screw of the microscope one can view the interior of the vertical canal with its granular lining cells for some distance, especially the oblique canals. The most typical specimens for studying the relations of the stomata vera of the endothelia of the free peritoneal surface to the subserous lymph channels came from the serosa on the abdominal side of the diaphragm of a rabbit which had been injected with a solution of carmine the day before it was killed. The carmine had obtained access to the subserous lymph channels and was impacted into stomata of the endothelia covering the lymph vessels. The carmine made them easy to observe, by reason of its red color. The frog shows the relations well in some specimens. The stomata vera may be found closed, partially or completely, or they may be found wide open. The frog and rabbit show typical specimens in regard to the degree of closure. Again, there is a condition of the stomata vera which induces endless discussion and many interpretations. In short it appears to me to be a condition in which the stomata are filled with granular material like grains of corn meal colored dark red. Is it not this condition that sorely puzzles Muscatello? He concedes they are stomata, but a kind of

closed stomata which allow passage of finely divided matter, when it really forces the granules apart and slips through. He claims that such stomata vera are just like the apertures in the walls of blood-vessels which every now and then allow the exit of a certain number of blood corpuscles. Of course it is easy to recall similar conditions asserted by Von Recklinghausen, when he said he could see whorls produced in the milk globules and see the milk globules duck into the peritoneal endothelia and disappear, but he never could find the real mouth which received the milk globule until he marked the spot of ducking under the milk globule and then allowed Ag No. 3 solution to

FIG. 18. — The Peritoneal Side of the Diaphragm of a Woman 26 years old. Dead three days. Ag No. 3. (Oc. 4, ob. 3.) The figure shows four stomata vera, 1, 2, 3, 4. Enormous numbers of stomata vera exist on the peritoneal side of the diaphragm, more than were found on the pleural side.

FIG. 19. — Drawn from the Pleural Side of Same Diaphragm as Fig. 18 (woman 26 years old). The figure shows three stomata vera, 1, 2, 3. No. 2 is wide open and Nos. 1 and 3 are closed, while No. 1 shows a slight mouth and No. 3 nuclei for two granular cells. No. 2 has six granular cells around its mouth. The stomata vera here (pleural side) are larger than in Fig. 18 (peritoneal side). 4, a granular cell or a cell much more browned than others.

trickle under the cover glass, when by its stain it showed at the marked spot the stoma verum but no open mouth. All that Von Recklinghausen could see was the dark granular cells marking the stoma verum, which had opened to allow the milk globule to pass and then closed, leaving no trace of an open aperture. It is like a swimmer diving in water: he has left no aperture behind—all is closed. Those who have watched frogs in a pond during the summer season will note the water entirely covered in places by green vegetation; the frog dives through this vegetation into the water beneath, but the springy vegetable matter closes immediately after the frog and no trace is left behind. This granular or filled condition of the mouth of the vertical canal is not well understood. It may be that the canal has an elastic sphincter and that an excess of granular cells exists at its mouth. Also the granular polyhedral cells themselves may entirely fill the stoma but the microscope be unable to discriminate the absolute outlines of the granular cells.

What are the functions of the stomata vera? First, the endothelium immediately surrounding them stains darker red than that more distant: so far as we know, this indicates more precipitate albumin, newer cells, or younger protoplasm. Hence it would appear that the stomata vera are the source of new endothelia to supply the ranks of dying comrades. Second, it appears to me from investigations that they are the regulators of peritoneal fluids. For example, if inflammation attacks the stomata vera, too much or too little fluid will prevail in the abdominal cavity. Inflammation of the granular cells which line the vertical canals—stomata vera—would enlarge them and obstruct the return flow of peritoneal fluid, resulting in ascites. The active condition of the stomata vera may account for the rapid death in perforative peritonitis, for the reason that they then quickly absorb the toxic matter existing in the peritoneum and transfer it immediately to the vast subserous lymph lakes of

the diaphragm. The stomata vera, as anatomic and physiologic structures, give at least a reasonable explanation of the existence and regulation of the peritoneal fluid. Ascites must of course rest on inflammation of the cells in the vertical canals or the stomata vera. The claim that stomata vera only exist on the diaphragmatic serosa of the peritoneum must be emphatically denied. Dubar and Remy claim that matter in the peritoneal cavity is absorbed by other regions, and no doubt this is true, though I have as yet found no absorption of carmine in the other portions sufficient to warrant this assumption. The claim that stomata vera do not exist as anatomic and physiologic structures is generally based on the idea that they are irregular in numbers and distribution; that large areas exist without a trace of them. Others claim that stomata vera are the product of Ag No. 3 or of some trauma. They are simply the results of precipitation in the intercellular substance. Muscatello even claims that they are the result of the retraction of endothelia and precipitation of the intercellular substance. Muscatello says the stomata vera are the same kind of openings as those which exist in the walls of the blood vessels, that will under certain circumstances allow the escape of many white blood corpuscles. This comparison makes no denial of the existence, only it belittles the high significance of the stomata vera. I at first thought that I would be able to note some especial difference in endothelia and stomata in different animals to account for the difference in resistance against peritonitis, but so far no light has broken on that subject. For example, the mare resists peritonitis so slightly that laparotomy is not practical and puerperal fever is rapidly fatal. So far as I am aware solipeds do not resist peritonitis well. Man and dog are about equal in this respect, while the pig resists peritonitis to a high degree. Yet so far the microscope has indicated to me no marked differences. Much stress is laid on the fact by some that irregularity in number and distribution contraindicates the stomata vera as being anatomical structures. It is true that anatomic structures are generally regular. The irregularity and distribution of the stomata vera may be acquired. Again, Schweigger-Seidel and Dogiel claim that the granular polyhedral cells projecting into the stomata vera are the nuclei of the group of endothelia surrounding the stoma verum. This I have disproved in many specimens, especially those of the embryo pig, in which the nuclei of the endothelial plates surrounding the stomata are distinctly shown in the cells themselves, far removed from the edge of the stoma verum. One might describe even two kinds of stomata vera, viz.: (a) the stoma verum which connects a lymph channel directly with the peritoneal cavity and (b) a stoma verum which leads into capillary lymphatics from the peritoneal cavity and has polyhedral granular-mouthed cells only at one end, the peritoneal opening being a simple aperture between endothelia (Klein). The most significant variety is those connecting the peritoneal and lymph trunks directly. I mention here a noticeable feature in the lymphatic channels of the diaphragm of a rabbit on the abdominal side. It is

FIG. 20. — From Frog's Lymphatic Cisterna Magna, Peritoneal Side. (Oc. 4, ob. 3, R.) It shows stomata vera mostly closed. 1 is open, the remainder closed. Ag No. 3, 1/2%. (It is very difficult to say positively that some are open, for the space is filled with granular matter which resembles the stomata-vera cells. The figure was sketched under good sunlight, as near to nature as possible.) 2, 2, endothelia; 3, a stoma verum, one of the cells of which shows a nucleus.

some that irregularity in number and distribution contraindicates the stomata vera as being anatomical structures. It is true that anatomic structures are generally regular. The irregularity and distribution of the stomata vera may be acquired. Again, Schweigger-Seidel and Dogiel claim that the granular polyhedral cells projecting into the stomata vera are the nuclei of the group of endothelia surrounding the stoma verum. This I have disproved in many specimens, especially those of the embryo pig, in which the nuclei of the endothelial plates surrounding the stomata are distinctly shown in the cells themselves, far removed from the edge of the stoma verum. One might describe even two kinds of stomata vera, viz.: (a) the stoma verum which connects a lymph channel directly with the peritoneal cavity and (b) a stoma verum which leads into capillary lymphatics from the peritoneal cavity and has polyhedral granular-mouthed cells only at one end, the peritoneal opening being a simple aperture between endothelia (Klein). The most significant variety is those connecting the peritoneal and lymph trunks directly. I mention here a noticeable feature in the lymphatic channels of the diaphragm of a rabbit on the abdominal side. It is

that the stomata are far more numerous in the wall of the lymph channel than they are on the peritoneal endothelia immediately over them. It may be that fluid material will pass through the inter-endothelial substance of the peritoneal serosa without a distinct aperture or stoma lined with distinct cells, but the apertures became more marked and distinct, yes, even lined by granular cells, when they reach the wall of the lymph channels. At least it is very evident in specimens which I have examined that the walls of the lymph channels show stomata much more frequently than the peritoneal endothelia which lie immediately over them. I may be deceived by the closure of the stomata of the peritoneal endothelia. The superior number of stomata in the walls of the lymph channels directly underlying the peritoneal endothelia, which has so few, would indicate more special use. It seems to me that it would indicate that fluid matter could more readily pass through the inter-endothelial substance of the peritoneal endothelium than it could through inter-endothelial substance of the lymph-vessel endothelium.

FIG. 21.—From Frog's Lymphatic Cisterna Magna, Cisternal Side. (Oc. 4, ob. 3, R.) Ag No. 3, 25. The stomata are closed. Specimens (a), peritoneal, and (b), cisternal, side are drawn from the same specimen. I first drew (a) and then reversed the slide and sketched (b). One cannot decide the difference of the stomata on each side in separate specimens. 1 and 2, stomata vera.

The subject of inter-endothelial material or space is all-important in the study of the free peritoneal surface, as it appears to me the chief physiology of the peritoneum lies in the inter-endothelial spaces. I noted above that the chief anatomical structure was located at the common junctions of several endothelial cells, stomata vera, and it appears to me that the chief physiologic function occurs through the means of this structure, *i.e.*, the regulation of fluid currents and the production of new endothelia. We also noted that on the single inter-endothelial lines there are black dot-like droplets, which are interpreted by Virchow as lymphoid cells; by Von Recklinghausen, Oedmannson, Klein, and others as connective-tissue corpuscles, whose function may be to produce new cells. They are known as stomata spuria. Now, besides stomata vera and spuria there is a large inter-endothelial space filled with matter which stains dark and brown with Ag No. 3. The precipitate produced by the Ag No. 3 solution, of one-quarter

FIG. 22.—Omentum of a Woman Aged 30. (Oc. 4, ob. 3.) 1, Stoma verum (it is really divided into a light half and a dark half, and both contain nuclei or glistening spots); 2, 3, 4, 5, germinating cells intensely browned with permanent nuclei (notice that besides the stomata vera 6 and 8 there are five other intensely brown cells, no doubt new germinating cells; many similar adjacent fields exist); 10, 11, 12, common flat surface endothelia. The interpretation lies in the stomata vera 6 and 8. It looks as if it was jelly-like, granular protoplasm and was precipitated, aggregated into clumps by the Ag No. 3. In cell 4 the nucleus has two nucleoli.

The centre of the line one might say is black, but the color of the line becomes brown as it recedes, *i.e.*, precipitated material on the endothelial plate is nearly always brown. It appears from the use of Ag No. 3 solution on the peritoneal endothelium that the endothelial line may be announced as black, while that on the surface of the plate is brown. Whether this is due to two different kinds of material, one for the surface of the plate and one for the inter-endothelial space, on

FIG. 23.—Horse's Omentum to Show Endothelia Grouping around a Stoma Verum. 1, 2, 3, Endothelia; 4, rift between cells (the endothelia appear to be new themselves; they are surrounded by long fields of new or germinating endothelia); 5, 6, show some of the adjacent growing endothelia; 7, stoma verum (oc. 4, ob. 3); 8, 9 show a field non-prepared which lies on the border of still newer germinating endothelia (6, 6); 9, rift between cells, *i.e.*, a shrinkage of the granular protoplasm.

which the silver solution acts differently, or whether it is due to the quantity being greater in one place than in another is still uncertain. It may be that a thin layer of albuminous substance appears brown and a thicker one dark. It may also be thought that the age of the material on which the Ag No. 3 solution acts is different. The matter on the surface of the endothelial plate may be older than the inter-endothelial matter. However, the inter-endothelial substance is a soft, semi-fluid material of an albuminous nature. It is pliable and yielding, allowing considerable motion to an endothelial cell without destroying its integrity of position or of function. It adapts the cells to strains and trauma without rupture. Really the endothelial cells are resting in a semi-fluid bed, and the inter-endothelial substance acts like a buffer in sudden motion. It endows the endothelia with power to suddenly alter their course, position, and relation without losing the integrity of structure and function. This inter-endothelial semi-fluid bed adapts itself readily to sudden changes, as in the filling and emptying of organs and vessels. In an overfilled bowel the peritoneal layer gives way first. I have proved that peritoneal rents occur first in overfilling of dog's

FIG. 24.—Gastro-Hepatic Omentum of a Woman of 45. Two vacuolated cells which are widely expanded, almost sufficiently to be called a lymph sinus. A has five stomata vera, B has two stomata vera, 2, 2; 3 another vacuolated cell begins. (Oc. 2, ob. 8 a, R.) Ag No. 3 applied. One of the best places to study vacuolation is on the adult human omentum, especially along the large trabeculae. 4, 4, 4 are very brown spots. In these germinal tracts the endothelia are of all sizes and shapes. This was taken from a region where numerous vacuolated cells existed of all sizes.

ter per cent. to one-half per cent., is considered to be an aluminous of silver. The precipitate begins slowly in fresh specimens and gradually increases in breadth from a fine, dark, irregular line, just perceptible with a high microscopic power, to a broad line extending even over the surface of the adjacent endothelial plate.

intestines, showing that the inter-endothelial substance is put to active service in dilatation and contraction of organs and vessels. The inter-endothelial substance shares in inflammatory attacks, for the endothelia desquamate, leaving only the pitted, semi-fluid bed, which can but feebly protect itself and because of its fluid nature absorbs the invading hosts. The endothelial plates are so adjustable and the inter-endothelial line is of such a magnitude that the endothelial plate has a considerable range of normal adaptability. To the anatomic and physiologic structures (stomata vera and spuria) found in the inter-endothelial semi-fluid albuminous bed must we look for new revelations in further research, which must be of an experimental order. If one places peritoneum in water and allows it to remain several hours, the inter-endothelial line appears to enlarge, *i.e.*, it appears to swell by absorption of water, and the reverse is true if one places the peritoneum in alcohol or formalin. When the endothelia are brushed off they leave an oval depression, but the inter-endothelial line is frequently left almost intact, and even it remains if

the sunlight carefully regulated with distilled water, one will soon be able to detect with the naked eye brown spots or patches, and when these brown patches are mounted in glycerin they are seen under the microscope to be chiefly composed of germinating endothelia. The young growing protoplasmic cell readily stains a dark brown with the silver solution. Germinating endothelia present all grades of cells from the polyhedral to the multiple-sided, sinuous-bordered cells. These germinating endothelia are apt to be found along large blood-vessels. Certain propositions in regard to germinal peritoneal endothelium may be made:

1. Germinal cells generally grow over the surface of the common endothelia of the peritoneum. They project entirely above the surface, so that even different foci are required for them and for the peritoneal endothelia.

2. The germinating endothelia are of all grades of size and shape.

3. Their common and typical location in animals is

FIG. 25.—Woman's Omentum Majus. Eight vacuolating cells. (Oc. 4, ob. 3.) 1, An endothelial cell on the bottom of the lymph sinus or capillary very much browned, as well as 2 at the bottom of another stomata verum in lymph sinus endothelia; 4, stomata at bottom of large sinus or vacuolated cell; 5, 6, 7, 8, 9, germinating endothelial cells around the circumference of the lymph sinus or vacuolated cells; 9 also shows the brown growing endothelia between and among the vacuolated cells. 7 is doubtless a karyokinetic figure. Note that the growing brown lymph endothelia of the vacuolated cells is continuous directly with the lymph endothelia (10, 11, 12, 13, 14, 15, 16) to the right, *i.e.*, these seven vacuolated cells will soon form a new lymph sinus or capillaries. The vacuolated cells are widening stomata.

FIG. 26.—Young Dog's Lymph Sinus, or well-developed vacuolated cell in a region of germinal endothelial cells. 1, 1, 1, Open stomata on the lymph sinus; 2, 2, 2, 2, endothelia covering the lymph sinus or vacuolated cells; 4, 4, 4 show the edge of the vacuolated cell or lymph sinus is brown and hence young protoplasm. Note the very brown endothelia surrounding the vacuolated cells (4, vacuolated cells. Ag No. 3). The vacuolated cells continue to multiply and form lymph sinuses. Observe how the endothelia enlarge as they diverge from the lymph-sinus border.

FIG. 27.—Drawn from the Mesentery of Frog. (Oc. 4, ob. 3, R.) The sketch represents a nodule of germinating endothelial cells elevated above the surface. 1 represents the stalk of the nodule; 2, the growing nodule; 7, one of the quite granular endothelial cells in the top of the nodule; 6, nucleus of common surface endothelial cells; 5, intra-endothelial stomata; 3, common surface endothelia. This stalk (1) of growing, germinating endothelial cells, of a protoplasmic character, is elevated above the surface of the common endothelia. Notice the grouping of cells in the nodule at 6.

the stomata spuria—black dots—seem to be left intact also: but for some reason the black dots on the inter-endothelial lines sometimes appear to increase in number. The stomata vera disappear on brushing.

The regeneration of peritoneal endothelia will be considered here only as it affects the normal peritoneum. It does not partake of the domain of pathology. The regeneration of peritoneal endothelia will simply be considered as a natural process whereby new endothelia are produced to supply the ranks of dying or worn-out comrades. The endothelia of the peritoneum are like a standing army which demands a steady recruiting to supply the various kinds of loss. The peritoneum being an organ of intense vascular and functional activity, its needs are vast, and they are fully supplied by what we shall term germinating endothelia. We might call these young as well as germinating endothelia, but I adopt the term germinating from Klein as an apt expression. One soon has the attention drawn to germinating endothelia in the microscopical study of the peritoneum. If epithelium from an omentum majus or gastro-splenic, fresh from man, rabbit, dog, or any animal we have so far examined, be carefully placed in a solution of from one-eighth per cent. to one-half per cent. of Ag No. 3 and

on the omentum majus and gastro-splenic. However, they may be found almost anywhere in the peritoneal sac.

4. The intense brown color they quickly assume on the application of a silver solution characterizes them as young, germinating, protoplasmic cells, with considerable precipitable albuminate.

5. They grow in irregular tracts, cords, or nodules, and are especially common about the edges of the lymph spaces and vacuolated cells.

6. The stomata vera will be considered as one of the chief sources and the stomata spuria as a secondary source.

The rabbit, dog, and man may be studied advantageously for excellent specimens of growing endothelia. Yet some very typical specimens I secured from the frog. For a long time I studied the germinating endothelia as to classification and am still unsettled as to the best, but we may simply describe the germinating endothelia as (*a*) nodules, (*b*) cords, and (*c*) patches. It may be that both cords and patches can result from the fusion of nodules. Accessible literature concerning germinating endothelia is not abundant: it is even very scarce.

In the first place it may be noted that the germination

of endothelium of the normal peritoneum differs from a pathologic process but little, and it may be very difficult even for an expert to make out the difference between germinating endothelium, *i.e.*, regenerating endothelium, and the proliferating endothelium of an inflammatory process. I think that in some cases it is impossible to decide on an omentum of some animals whether the process is actual regeneration of germinal endothelia or the result of a chronic peritonitis. This paper is entirely confined to normal and regenerating germinal endothelia. Neither do I wish to enter into questions relating to the subperitoneal lymph vessels, except so far as to discuss the very significant vacuolation of cells—a step in the process of proliferating or multiplying endothelial plates.

Active germinating endothelia may be found on the omentum of man, frog, dog, and rabbit, in some of which it is rich and abundant. Splendid specimens of germinating endothelia may be found on the lateral portions of rather wide trabeculae. If one place

variable in extent. The cells may be single, in rows, or united into large patches. The new growing cells may have one, two, or three nuclei.

The patches or tracts of germinating cells are only the result of fusion of the cords. The blood-vessels of these patches are not easy to make out in their relations and development. Neither have I fully satisfied myself in regard to the nerve supply in its chief relations.

A feature in regard to the germinal endothelia is that they are not so easily differentiated from the normal. The normal endothelia are very easily broken away from their attachments. For example, by the slight trauma in carrying portions of the peritoneum of cows and sheep fresh from the slaughterhouse to the laboratory, the normal endothelium is badly desquamated, but the germinating endothelium is so much more adherent that it is more easily and accurately studied.

Conclusions.—1. The endothelium is the essential structure for physiologic function of the peritoneum.

FIG. 19.—Human Omentum of a Woman Thirty Years of Age. Dead twenty-four hours. Ag No. 3. (Ob. 3, oc. 4.) The lightly shaded common endothelia and the darkly shaded germinating endothelia which are growing up over the surface require different foci. 1, 1, Common endothelia; 2, 2, germinating endothelia; 3, clumps, debris; 4, lymph or capillary sinus with a stomata verum seen at its bottom; 5, stomata verum. This figure shows merely the formation of a lymph sinus in the midst of germinating endothelia. 4 is a vacuolating cell which will eventually end in a lymph vessel.

FIG. 20.—Omentum of Woman Aged Thirty, Twenty-four Hours after Death. Ag No. 3. (Oc. 4, ob. 3, R.) This is an interesting specimen, showing two vacuolated cells. 1, 2, 3, 4, 5, show the common endothelia brushed off and lymph endothelia irregular and many stomata spuria; 6, 7, 8, 9, 10, 11, stomata vera of lymph capillaries. 1, 2 are become lymph sinuses or capillaries. The endothelia adjacent to the vacuolated cells 1 and 2 (or lymph sinuses or lymph capillaries) are chiefly of a germinal character, but some resemble common endothelia in character.

FIG. 30.—From Rabbit's Omentum Majus. A typical lymphatic sinus surrounded by typical germinal endothelia. 1, 1, 1, The lymph or capillary sinus; 2, 2, a secondary lymph sinus; 3, 4, 5, 6, 7, the germinal endothelia (note the three elongated cells at 8; 9, closed stomata verum). It appears that such lymph sinuses arise by the vacuolation of cells; the cells by repeated vacuolation form large, numerous, and irregular endothelial plates; here they have really become a lymph channel. (Oc. 4, ob. 3, R.) This drawing is taken from a vast region of germination. Note how the endothelia enlarge as they recede from the sinus, 1, 1, 1.

under the microscope a portion of a frog's mesentery, mounted in glycerin, the typical germinal growths may be observed. First, one may note nodules or club-shaped bunches of endothelia projecting above the common surface endothelia. The nodule or club has a small constricted neck or stalk, which starts distinctly from its common surface. Some have the shape of a half-sphere and the flat surface rests on the endothelia. The stalk appears to me to have its origin from (a) stomata vera, (b) stomata spuria, (c) from the circumference of a lymph sinus. The lymph sinus may be a vacuolated cell. It seems that the endothelial cells have grown in such a shape as to fit the nodule. Sometimes the nodule resembles a cone. The stalk may be composed of one or several endothelial cells. Two nodules may originate from the same point, and this fact induces me to consider both stalks as originating from a stomata verum. In some specimens may be observed cords of germinating endothelia. They run in various directions, but they lie chiefly on the circumference of lymph sinuses.

No doubt such areas of germinating endothelia are what Klein designated as perilymphangeal. The vacuolating cells seem to multiply the endothelia indefinitely and thus form new lymph channels and sinuses. The endothelial cells growing from the circumferences of the areas of vacuolated cells are very

2. The peritoneal endothelium lines an enormous lymph sac, which originated from fluid pressure and independent motion of viscera and body wall.

3. There are four distinct elements in the free peritoneal serosa, *viz.*: (a) the endothelial plate, (b) the stomata verum, (c) the stomata spuria, (d) the inter-endothelial substance or space.

4. The endothelium is an elastic connective-tissue corpuscle, flattened and smooth on one side and oval or irregular on the other side, with various processes jutting from it. It contains a sharply defined nucleus, centrally or excentrically located. The plate is covered by an albuminous, semi-fluid substance, which is precipitated by Ag No. 3 and is probably originally polygonal in shape. However, the plate acquires a very varied shape from living forces. It contains a reticulated network. There are certain apertures in the plate which I have designated intra-endothelial stomata, but so far I have not been able to define their structure or function. It may be such intra-endothelial stomata are the result of trauma or of reagents. The utility of the peritoneal plate is in permitting maximum motion with minimum friction; it also allows the location and fixation of friction of inter-endothelial structures, *i.e.*, an adjustable bed of inter-endothelial substance, stomata vera, vertical canals to regulate fluid currents and grow endothelia, with stomata

spuria, which are additional points where endothelium can renew itself.

5. Stomata vera are vertical canals located at the common junction of several endothelial plates lined by germinal, granular, polyhedral nucleated cells. The canal opens with one end in the peritoneal cavity and the other end into the subperitoneal lymph channels. A second kind of stomata vera is those which represent simply a discontinuity between the peritoneal endothelia, with no mouth lined by granular cells but with the subperitoneal end opening into lymph spaces and lined by granular polyhedral cells. These stomata vera or vertical canals regulate fluid currents and are the source of new endothelia. The septum cisternæ lymphaticæ magnæ of the frog shows typical examples. It may be that rapid death from perforative peritonitis is caused by the stomata vera quickly absorbing toxic microbes. The stomata vera appear to possess an elastic sphincter to control the degree of opening or closing of the mouth. The granular cells of the stomata vera on the application of Ag No. 3 become dark brown or reddish, which doubtless indicates that they contain more precipitable albumin than the adjacent endothelia.

6. The stomata spuria are located on an inter-endothelial line. The application of Ag No. 3 produces a black dot or droplet-like appearance. The stomata spuria are probably connective-tissue corpuscles or the processes projecting upward between the endothelial plates. They have been compared to lymphoid corpuscles. They are not likely to be accumulated products of reagents or of trauma. They are no doubt also sources of new endothelia.

7. The chief arguments against the existence of stomata vera and spuria in the peritoneal serosa are their irregular distribution and number and also that they are accidental products or trauma or reagents. The argument may be proposed that the stomata vera or spuria are not preformed openings, but are the result of dragging and widening of the intercellular substance due to motion of the abdominal wall and viscera. Through these openings red and white blood corpuscles and leucocytes may find passage, in consequence of circulation disturbances. It may be asserted that the stomata spuria are only a sudden widening or enlargement of the inter-endothelial lines.

8. The inter-endothelial substance is a semi-fluid, albuminous material which becomes black or brown by the application of Ag No. 3. The inter-endothelial lines appear to thicken and broaden as they descend toward the subendothelial tissue. It exists chiefly in the form of a thin, straight, curved or sinuous line between the endothelial plates. The size of the line depends on the strength and duration of the Ag No. 3 and sunlight. The soft, yielding semi-fluid material in which the endothelia rest allows a wide range of movement and considerable adjustability of the plate; also it permits the plate to assume varied shapes to suit environments and correlation of forces. It adapts the endothelia to sudden motion, acting as a buffer to prevent trauma. It no doubt allows fluids and even solids to pass through it, either toward the peritoneal cavity or toward the subperitoneal lymph channels. The inter-endothelial substance is the seat of the physiology of the peritoneal serosa, as it has located in it structures known as the stomata vera and spuria.

9. So far as my experiments in intraperitoneal injections and microscopical examinations are concerned, the diaphragmatic serosa is the only territory where the material is absorbed. However, both my experiments and microscopical examinations are too limited for any definite conclusions. The reasons for the diaphragmatic serosa being the only region where material is absorbed are given by Bizozzero, Salvioli, and Mus-

catello as due to the anatomical fact that the membrana limitans possesses perforations only on the serosa of the diaphragm. So far, I am not definitely able to confirm the above opinion of apertures being confined to the membrana limitans exclusively, but certainly stomata vera do not appear any different on the diaphragm than they do in other regions.

10. The absorption of organic and inorganic finely divided material being confined chiefly to the diaphragmatic serosa, it seems that a stream must be directed toward the diaphragm, which may account for rapid deaths in perforative and other kinds of peritonitis. The idea of a current toward the diaphragm is based on the result of experiments; e.g., carmine suspended in fluid is what I employed to inject into the rabbit's peritoneum and the red granules could be found in the subserous region of the diaphragm, especially in the large-branched connective-tissue corpuscles and the lymph channels.

11. The views of Muscatello, that the peritoneal serosa is normally a continuous sheet or surface without any apertures except those made when leucocytes force their way through the soft intercellular substance, which apertures may persist, I do not consider in accord with experimental and microscopical evidence. Certainly the stomata vera found on the sheep's mesentery or the frog's cisterna lymphatica magna are absolutely and distinctly anatomical structures, and cannot be reasonably interpreted as merely temporary apertures produced by a few leucocytes forcing themselves through the inter-endothelial substance. No number of leucocytes forcing their way through inter-endothelial substance would leave behind an aperture lined by distinctly granular, polyhedral cells capable of being outlined by a microscope.

12. In our labor on the peritoneum of man, the horse, bird, dog, pig, cow, sheep, rabbit, frog, and embryos of pig and man, it was observed that the endothelium of the peritoneum was easily desquamated by trauma and inflammation. In many specimens of tubes, ovaries, and uteri which Dr. Lucy Waite and I removed, by immediately staining with Ag No. 3 it was found that the inflammation of the organs and the accompanying trauma of removal nearly always desquamated the endothelia so much that it destroyed the specimens for proper study. Severe inflammation desquamated almost every plate from its bed.

13. The structures located in the free surface of the peritoneal endothelium show powers of rapid absorption, and hence free drainage of the abdominal cavity is the prophylaxis against invading septic peritonitis.

14. Beck¹ experimentally demonstrated and confirmed the well-known clinical fact that the peritoneum absorbs material more than three times faster than the pleura. In opening bodies in autopsies it is well known that inflammatory pleuritic bands are far more numerous than inflammatory peritonitic bands. The reasons that inflammatory pleuritic bands are in excess of peritonitic bands is that the slower absorptive power of the pleura allows ample time for exudates to form. If the pleura or the peritoneum is given time to oppose the invasion or absorption of material protective exudates arise. The rapid absorptive powers of the peritoneum, over the pleura, is an important clinical fact, and in all probability is due to the inter-endothelial structures, viz., stomata vera and spuria, and also its extensive inter-endothelial substance.

NOTE.—Since the above article was written I have consumed several months of investigation on the inter-endothelial substance or space in quite a number of animals, employing the one-fifteenth oil-immersion lens (Reichert), and the reagents Mueller's fluid, osmic acid, and tannin. The investigation has induced me to discard the term inter-endothelial substance and to substitute

¹ Wiener klin. Woch., 1893, No. 46.

for its inter-endothelial space. The dark inter-endothelial lines are capable of being dissolved into two lines, each one bordering on the edge of the cover plate. Also, these two parallel lines show numerous anastomosing protoplasmic processes passing transversely from one to the other. The hypothetical inter-endothelial cement substance is dissolved into a network of anastomosing processes, and hence we will hereafter speak of a space and not a substance. The anastomosing processes belong chiefly to the lower portion of the endothelial cell, *i.e.*, the protoplasmic part. The cover plate or metamorphosed indurated portion has but slight connections with the anastomosing processes. The suggestions of Dr. A. Kolosow, of Moscow, Russia, induced me to employ osmic acid and tannin as fixation and reduction agents. The effect of these reagents is to produce specimens by means of which more definite observations can be made and conclusions drawn. The investigations show that the endothelia of the peritoneum are connected organically into cell colonies.

SOME FORMS OF NON-OBSTRUCTIVE ISCHURIA.¹

By ALEXANDER W. STEIN, M.D.,

NEW YORK.

INABILITY to empty the bladder may be due to

1. Atony of its muscular parietes, or to

(a) Deficient contractile power of the so-called detrusor from overstretching of its fibres (duration usually temporary).

(b) Loss of power of detrusor from atrophy and fatty metamorphosis (duration permanent).

2. Neurotic retention, or

(a) Deficient power of the detrusor concomitant with some psychical or other functional disturbance of the nerve centres, *viz.*, alcoholism, narcotism, stupor, etc. (duration temporary).

(b) Paresis, or cystoplegia, due to organic derangement of the nerve centres (duration usually permanent).

3. Spastic or reflex retention, due to irritation from some neighboring organ, inducing sphincterismus (disappears with the cause that produced it).

The degree of atony resulting from overdistention of the bladder may vary from a slight and temporary impairment in the expulsive power of the bladder to a complete and permanent inability to empty its contents, depending upon the age and health of the person, the condition of the bladder, the degree of distention, and the length of time the detrusor fibres have been upon the stretch. In the aged and feeble this condition is not uncommon, and permanent disability of the viscus often results from a single inattention to its behests. In the young and robust atony is much less frequent, and the bladder once relieved of its burden regains its functional activity. We may recognize five stages or degrees of atony:

1. An enfeebled expulsive action of the bladder.

2. Retention relieved without catheterization.

3. Retention relieved after single catheterization.

4. Retention requiring repeated catheterization.

5. Retention requiring continued catheterization.

We have perhaps all experienced the momentary difficulty of micturating that obtains when we have permitted the bladder to become unduly distended. Availing ourselves of the first opportunity for relief, we find the flow occurs only after a moment's hesitation, requiring some effort to start it, and when the stream comes it is at first small and feeble, increasing in force as the sphincters relax and the detrusor fibres regain their power. Regarding the other forms of retention, I recall some typical phases that may serve to furnish the practical data for the above title. It will be observed that in these, as in most cases of atony, the impaired motility was preceded by a deficient sensibility of the bladder.

A middle-aged gentleman has on several occasions

during the past few years, when much engrossed in business affairs and neglectful of self, suffered from attacks of retention. His bladder fills to a degree without creating any marked discomfort, after which a sudden and urgent desire to micturate comes on. He suffers greatly with tenesmus and strains ineffectually until he gets into a hot sitz bath. Thus the necessary relief is always afforded and he has never been obliged to resort to catheterization.

A prominent politician, a free liver in an alcoholic sense, consulted me because he thought there was something wrong with his "waterworks." He had no pain, at the most a vague feeling of having imperfectly evacuated the bladder, and on coughing or sneezing stillicidium would occur. This was the first and only intimation he had of something being wrong, and he sought advice for what he affirmed was an inability to hold his water. There was no mechanical impediment, but on palpation it was found that his bladder was distended up to the umbilicus. He was so sceptical on this point that I asked him to evacuate the bladder as much as possible by his unaided efforts, and I would demonstrate to him that his bladder was still surcharged or in a waterlogged condition. It was certainly a great temptation to relieve him at once, because he could not be made to realize his condition; but it was not done. Incidentally it may be mentioned that he died somewhat suddenly some months afterward, and at the autopsy all there was found of one kidney was its fibrous capsule, the excreting elements were completely atrophied. The other kidney was in the condition of compensatory hypertrophy; there was no calculous history. In one instance the bladder will be but slightly distended and occasion more urgent symptoms than in one in which it has risen above the umbilicus. In the latter case the nerve endings of the vesical neck, never very sensitive perhaps, require only a slight cause, such as vicissitudes of temperature, free indulgence in spirits, etc., to obtund them still more. Expulsive factors, both muscular and nervous, are always very feeble when compared with the retentive factors, as only the latter are directly subject to sensation and volition.

The frequency of micturition is not alone due to the quality of the urine, as I think we in practice too often imagine it to be, but it depends in a great measure on the degree of tonic contraction existing in the vesical walls, which contraction is at first augmented as the muscular fibres are subjected to tension. The retentive and expulsive factors are so admirably adjusted one to the other as to bring about a harmonious sequence of action, and the feebly developed detrusor will gradually accommodate itself in power to any embarrassment to the escape of urine so long as the vesical neck retains its sensibility; but as soon as this is lost the fate of the patient is in most cases sealed. The thin, pale, flaccid, and insensible detrusor, associated as it often is with feeble health or exhausting disease, only requires to be once overstretched to become permanently atonied. If the muscular fibres have undergone no structural change other than overstretching, they will of course recover their tone more readily than when atrophic or fatty changes have involved their texture, which is the frequent outcome of old age, and in such cases recovery is obviously not to be anticipated. A gentleman of spare build and feeble health, while out yachting with a party of ladies, was obliged to hold his water all day, and when he got a chance to micturate found that he could not do so. He had not passed his urine except through the catheter from that time to the day of his death, more than twenty-six years. He was then about eighty years of age. In this instance there was no obstructive or mechanical impediment to the escape of urine at the time of the advent of the trouble, and

¹Read before the American Association of Genito-Urinary Surgeons, June 1, 1896.

but slight concentric hypertrophy of the prostate when I examined him, twenty-three years afterward. The too sudden removal of the hydrostatic tension was apparently responsible for the mischief. This, though an exceptional case, impresses us again with the lesson that we have repeatedly learned that the length of time taken to empty the bladder should at least approximate to the length of time that overdistention has existed. Secondary retention is always to be feared when the bladder has once suffered prolonged distention. Hence catheterization should be repeated until the bladder manifests its accustomed expulsive power by the force and volume of the stream and is apparently free from residual urine. A good manœuvre, which will sometimes succeed and should always be resorted to, is to pass the catheter as far as the vesical neck, allow it to remain until it begets the desire to urinate, and then quickly remove the instrument. The bladder is thus coerced, as it were, to perform its natural function.

In some persons the only confession that nature makes of a neurotic temperament is through the uropoietic viscera, while others of the same family who may be decidedly neurotic show no disturbance whatever in this respect. The surplus of nerve force not taking the habitual channels expends itself upon the sphincters in an efflux of motility, producing what we term sphincterismus. In some instances the patient will tell us that when he has the desire to micturate he feels a sense of constriction at the vesical neck, which he finds impossible to overcome with the most powerful effort of the abdominal muscles and diaphragm, and is obliged to wait until a momentary relaxation of the sphincters occurs. Thus spasm and relaxation alternately recur a number of times during an act of micturition. Such persons are apt to suffer from dysuria with partial retention. A gentleman, aged thirty-five, was in such a high state of nerve tension while on shipboard that he could not pass water except with the aid of the catheter in either of his trans-Atlantic trips, though he never experienced the slightest difficulty while on terra firma. In him the inhibitory influence on the vesico-spinal centre was very apparent and effective.

A maiden lady said she never felt the natural impulse to micturate, and did so morning and evening more from habit than from necessity. She was subject to hysterical attacks about the time of her menses, when she indulged pretty freely in whiskey. I was invariably summoned in the dead of night, and would find her in a condition of semi-alcoholism, suffering from retention of urine. There was so much vaginismus that extreme delicacy of touch had to be exercised, and so much sphincterismus that the catheter was felt to be firmly grasped at the vesical neck. Upon the introduction of the instrument an enormous quantity of pale limpid urine escaped. For five consecutive months, at almost precisely the same time, this séance had to be repeated, until she was considerate enough to go South. She never required but one catheterization for each attack.

An elderly gentleman, somewhat ataxic, says that for a period of years he has noticed a gradual but steadily increasing difficulty in emptying his bladder. He ascribes his trouble to an attack of paresis which he had ten years ago. There was at first simply a hesitation in micturition, with an enfeeblement of the expulsive power. This increased until for more than two years he has not been able to micturate without exerting the full expulsive action of the diaphragm and the abdominal muscles. He dreaded instrumentation and was inclined to leave pretty well alone, but about six weeks ago, coming home from the club one night, he had absolute retention, for the relief of which he called to his aid a well-known surgeon who

lived near by. Up to this time he was free from cystalgia, the urine remained uniformly clear, there was no undue frequency in micturating, and hence he leaves nothing to the imagination in his phraseology in saying that his present condition, with excruciating pain, great frequency in urination, broken rest, and offensive, ropy urine has been brought about by the dirty catheterization of his former surgical attendant. This is an experience which you can doubtless multiply. The long-suffering, patient bladder copes successfully with the enfeebled contractile powers, until retention occurs or residual urine accumulates, necessitating artificial means for relief, when at the same time the pathogenic spark is introduced, which sets up a conflagration in the viscus not readily extinguished. This case stands in a striking contrast to another one above cited, in which the bladder was indifferent to septic germs, and tolerated with apparent equanimity rude instrumental manipulation for more than a quarter of a century.

"Strange! that a harp of a thousand strings
Should keep so long in tune."

Urine is and will remain aseptic so long as certain micro-organisms do not have access to it and remain in contact with it long enough to effect the hydrolysis of the urea. If the bladder is capable of completely emptying itself within a few hours of the introduction of these organisms they will not have time to induce the fermentative process, but if some change exists in the physiognomy of the viscus whereby it will contain residual urine they will find a most favorable culture medium prepared for their reception and multiplication, and the attendant sequelæ are to be anticipated. This latter patient had either a vulnerable spot on the vesical mucous membrane which the pyogenic organisms could invade directly, or, which is more probable, the viscus was incapable of thoroughly discharging its contents. Fermentation of the urea ensued, irritation and inflammation resulted. Another noteworthy point in this case was the enormous manufacture of mucus. The production of so much mucus in so short a time from a membrane devoid of goblet cells and with but few and very minute racemose glands, is a fact most interesting in the metabolic activity of the bladder.

Hence, to prevent microbic infection, we have, first, to be scrupulously careful in having the instrument and lubricant employed in a thoroughly aseptic condition, particularly in cases in which the bladder is suspected to contain residual urine. Most atonied bladders, especially those of elderly subjects, will contain residual urine after ordinary catheterization, unless this is effected with the patient in an erect posture, which for obvious reasons is not done. In the recumbent attitude, the bladder manifests its loss of inherent power by the slow and feeble character of the stream, which discontinues often before the viscus is half empty, requiring firm pressure over the hypogastrium to renew it. Second, we reiterate the injunction not to remove the internal tension too soon, particularly because of the hyperamia of the mucous surface which it occasions, whereby the most favorable environment will be obtained for the development of the pyogenic germs. Third, to inject an antiseptic solution after each catheterization, especially at the finish, and to aspirate and irrigate the bladder as a prophylactic measure. For the microbes of ammoniacal or catarrhal cystitis may be destroyed betimes; not so when the pyogenic organisms have invaded the submucous coat, producing suppurative cystitis. Then we have a much more aggressive and intractable matter to contend with.

Various local conditions, some of which have already been described, may reflexly induce spasm of the

extra- and intra-pelvic sphincters sufficient to cause retention. The bladder often manifests its sympathy with neighboring organs when in trouble; it cries out in painful tones, enduring the burden of a disease located elsewhere, of which it is entirely innocent. I call to mind a strikingly illustrative case in which sphincterismus with retention was induced by a deep stricture of large calibre, which was relieved by the relaxing effect of ether. Frequent but unsuccessful attempts at catheterization had been made at intervals by adepts, and it was decided to perform external perineal urethrotomy without a guide. The patient was anæsthetized, brought into the amphitheatre, put in position, and the staff introduced. The operator was about to make the incision, when to the great astonishment of all present, the instrument glided into the bladder with the utmost facility. A catheter of larger size was immediately substituted and introduced with equal facility, and the bladder emptied.

Although somewhat irrelevant to the subject in hand, I am impelled to speak of a recent experience. It was a case of retention due to a periurethral abscess located in the perineum. The man was thought to have a tight stricture, ulceration of the urethra, and extravasation of urine. In this belief he had been repeatedly but unsuccessfully catheterized with small instruments. When I saw him there was unmistakably some extravasation, but no stricture was apparent. If an abscess exists in the perineum associated with difficult micturition, the sooner it is evacuated the better, and this should always be done before instruments are introduced, otherwise a urethral communication may be made with the abscess, endangering extravasation of urine, as obtained in this case.

MÉNIÈRE'S DISEASE—APOPLECTIC FORM.

BY THOMAS A. KENEFICK, M.D.,
NEWPORT, RHODE ISLAND.

FOR many years Ménière claimed to have seen certain cases with such decidedly characteristic localized and reflex symptoms as to convince him there existed a lesion, the pathology of which alone remained to be demonstrated.

His opportunity came in 1861, when his patient died after an illness of five days, during which she exhibited the typical symptoms of this rare disease. He then showed in this case that the lesion was a reddish plastic exudation into the mucous membrane and labyrinth of the internal ear, there being no other evidence of trouble.

Previous to this demonstration, we read, he was convinced of this lesion, as men are frequently to-day with other diseases, in which a diagnosis of the pathological changes is borne out by the symptoms, making a post-mortem examination almost an unnecessary requirement.

Still, with these facts in view, doubt is frequently expressed from different parts of the world as to its real existence, owing possibly to its exceedingly rare occurrence in the true apoplectic form.

It must be admitted that with the light of our present knowledge of anatomy and physiology, together with the art of physical diagnosis, if we are given certain well-marked, definite, and localized symptoms associated with and pointing exclusively to a limited and special area, we have collected all the knowledge required for a correct and scientific diagnosis.

A consideration of the lesion and the physiology of the immediate and distant effects is a preliminary necessary to a claim for the report of a case of this character, in which sudden deafness, vomiting, and dizziness were the prominent and only phenomena.

The anatomical parts involved and affected are the membranous labyrinth, and the terminal endings of the auditory and vasomotor nerves. These terminal endings are not distributed generally over the membranous surface, but in well-defined spots characterized by a thickening and by peculiar epithelia provided with stiff pointed cilia, called auditory hairs, whose function is to aid in the transmission of sound waves. It can be readily appreciated how a sudden exudation into and upon this membrane would prevent at once the further performance of this function.

Högyer affirms that these same terminal endings from their communication with the cerebellum form an apparatus which regulates according to the position of the body the movements of the eye and probably those of all the muscles exerted in the preservation of equilibrium.

This theory is also shared by Moos, Löwensky, and Politzer. So that for the giddiness we have only to trace the auditory nerve to its connection with the cerebellum, this being the main peculiarity which distinguishes this one from all the other cranial nerves. The vomiting and perverted vision are then accounted for by reflex action through the ocular and vasomotor system. Trousseau has noted a giddiness similar to that of Ménière's disease dependent upon a chronic gastric catarrh, proving the close relationship existing between the stomach and these same terminal endings. The accompanying report, I trust, may add a little to our limited knowledge of this subject.

On the morning of September 22, 1895, I was called to see a Mr. J—, and found a man about forty-five years of age, robust and healthy in appearance, unmarried, and by profession an architect. He was then fairly comfortable and gave the following brief history: He had always been perfectly well; he had no history of disease, specific or otherwise, and since childhood he had lived a careful and regular life. I learned, however, that he had been an indefatigable worker. Besides attending to his profession during the day he applied himself to developing ingenious devices long into the night. Many of these have been patented and are successful. This mode of life he had carried on for more than twenty-five years with hardly a single day's holiday or interruption.

The previous night he was suddenly aroused during sleep by a most violent attack of vomiting, consisting of large quantities of dark greenish fluid accompanied with persistent and alarming dizziness. There were noises in the ear on the right side and also marked deafness. A thorough physical examination found him in splendid general condition, with no rise in temperature, no pain, no disturbance of the different reflexes, nor of motion or sensation. Microscopical examination of the urine gave negative results. Examination of the tympanum on the affected side showed a slight congestion of this membrane. The vomiting and dizziness continued for several hours, then ceased, only to return again the instant he attempted to raise his head or even turn it from side to side. The vomiting yielded finally to small doses of ipecac, but the dizziness and deafness persisted, the latter being absolute on the right side. In addition to these were certain symptoms of perverted vision which may or may not be of importance, but as a matter of interest I report them. He saw by his bedside the slanting roof of a conservatory on which sat a glazier rapidly fitting in panes of glass. The moment the glass was laid, it slipped through, when the glazier would quickly try another with the same result. This scene continued until the afternoon, when it was replaced by the figure of a woman dressed in brilliant red. At first the figure was short in stature but gradually increased in length until it appeared one hundred feet high and seemed to be surrounded by millions of active little

nice. These disturbances vanished toward evening, and but for the dizziness he appeared perfectly comfortable.

With these localized and sudden symptoms, and the absence of any general disturbance, in a previously strong and healthy man, this diagnosis was therefore decided upon. In this condition he remained, the slightest attempt to rise giving him the sensation as if he and the bed were rapidly revolving. The vomiting ceased, but the deafness remained until about two weeks, when this and the giddiness gradually improved, and at the end of six weeks he managed with a tottering gait and by the assistance of a friend to daily reach his office, which he persisted in doing until he fully recovered.

The treatment consisted of at first large doses of quinine and later a combination of bromide and iodide of potash, but with no marked success. Galvanism was applied and really seemed to give decided benefit and was persisted in, though I am of the opinion the disease ran an independent course toward recovery, with possibly some assistance in the process of absorption by the electricity. I have seen this man within the past few days and he assured me that all the symptoms have disappeared and that his recovery has been complete.

The diagnosis was made on the presence of these three distinct symptoms produced evidently by a lesion such as Ménière discovered, and which, by direct and reflex action and according to physiological teaching, is traceable and confined to the region previously described.

Progress of Medical Science.

Abnormal Labor Pains and Their Treatment.—

Dr. Schaeffer, we are told in an article summarized in the *American Journal of the Medical Sciences*, divides abnormal labor pains into those which are purely atonic and those which are partially spasmodic in their character. There have been various divisions made of atonic pains, some referring them to the various portions of the uterus, and others dividing them according to the degree of atony which is present. The uterus contracts more frequently when atony is present, but much less effectually. Such pains do not increase in vigor as dilatation advances. The pauses between these pains are shorter than in normal cases. In the latter portion of the period of expulsion atonic pains are more frequent and longer than in normal cases, so that in some patients the same effect is produced, although in longer time, which is obtained by normal pains. The amount of actual work done by the uterus is found by careful observation to be much greater than in cases of normal contraction. The work done by the uterus is most efficient in the first portion of labor: while compensation is wholly or largely effected in the latter part. It is observed that the latter portion of birth in these cases is practically accomplished by contraction of the abdominal muscles, and that these contractions are greatly influenced in a reflex manner by uterine pains. The diagnosis of atonic pains is often neglected, and this condition is mistaken for other complications. In partially tetanic pains there is no special delay in the rupture of the membranes. The most frequent cause of this condition is endometritis of the cervix, resulting in slow dilatation and increased suffering. Another cause of this condition is frequent examinations during labor, and the irritation which they produce. An abnormal position of the uterus may also produce partially tetanic contractions. The treatment of this condition consists in placing the patient in a favorable posture,

in the use of warm baths, and in hot vaginal douches. For weak pains, when simple atony of the uterus is present, small doses of ergotin, given by hypodermatic injection, are found useful. It was observed to produce an effect in about eight minutes after its administration.

The Leucocytes in Tuberculosis.—Drs. Stein and Erbmann have made a new study of this subject, based on the accurate observation of sixty cases. In many of these the clinical diagnosis was confirmed by post-mortem examination. In counting the white corpuscles a modification of the method of Thoma was used, in which, instead of counting the corpuscles in the squares of the blood counter, all those in a number of fields were counted, after estimating the contents of the space covered by the field. For many interesting details the original should be consulted; the following conclusions give the most important results: In beginning phthisis the number of leucocytes is normal. In advanced cases, but in which cavity formation has not taken place, the number is also normal. After attacks of hæmoptysis there is usually moderate leucocytosis, which disappears after the cessation of the hemorrhage. In advanced tuberculosis with chronic infiltration, but in which destruction of tissue is slight or has not yet begun, the leucocytes may be normal. Increase of leucocytes is encountered in cases with cavity formation, in cases with chronic suppuration as the result of carious processes, in final exudative processes, and in cases with hyperplasia of lymph glands. As regards cavity formation the following statements are important: If leucocytosis occurs in a tuberculous case in which there is no chronic suppuration and no exudation, ulcerative change, i.e., cavity formation, may be diagnosed. If in a case with normal leucocytes for a long time an increase takes place, excavation may be concluded. So long as the leucocytes are not increased the existence of a cavity, at least one of considerable size, may be excluded. The cause of the leucocytosis is not the tuberculous poison itself, but a secondary infection, a septic process, which may be the result of various bacteria.—*Deutsches Archiv für klinische Medicin.*

Pneumonotomy.—From an article published in the *British Medical Journal* we learn that Dr. Quincke has tabulated and analyzed fifty-four cases of pulmonary abscess treated by surgical operation. These cases, seventeen of which were treated by the author, are arranged in three groups: the first of acute abscesses, both simple and gangrenous; the second of chronic abscess and putrid bronchiectasis; and the last of putrid suppuration caused by a foreign body in the lung. In a large proportion of the fifty-four cases (eighty-three per cent.) the inferior lobe of the lung was the seat of the disease. Of the total number of patients, twenty recovered and twenty died: in the remaining fourteen cases, the surgical treatment either failed altogether or gave but imperfect results. The author makes out from his collection of records that while the mortality from operative interference is almost equal in acute and in chronic cases, the percentage of complete recoveries is higher by about forty-five in the former than in the latter. It is concluded that the operative treatment of acute pulmonary abscess will be attended with complete success in two of every three cases. The prognosis of such treatment in cases of chronic, and especially putrid, abscess is much less favorable. The author believes, however, that in future better results may be attained by earlier intervention. Surgical treatment, he holds, is indicated in cases of acute abscess which show no tendency to spontaneous healing. The prospects of an operation in such cases are better than those of an expectant treatment. If such suggestion be generally

followed chronic pulmonary abscess with secondary bronchiectasis will, it is thought, less frequently be observed. Notwithstanding the less favorable prospects of operation in cases of chronic pulmonary abscess and sacculated bronchiectasis, such treatment is here recommended for these morbid conditions with the view of protecting against acute secondary inflammation the portion of lung still remaining sound. In cases of multiple bronchiectasis, although *a priori* a good result could hardly be expected from surgical operation, still, the author thinks, improvement may be brought about by such treatment. As such a condition constantly threatens fresh and fatal mischief, an operation, though not clearly indicated, need not be regarded as unjustifiable. In discussing the diagnosis of pulmonary abscess the author regards as important indications the purulent nature of the expectoration and the presence in the discharge of minute portions of broken-down lung tissue. The quantity of expectorated fluid, he points out, affords no sure indication of the size of the cavity. In considering the diagnosis of the seat of a supposed pulmonary abscess, he states that when on general grounds the existence of such a cavity is assumed, and a localized area of dulness exists without any distinct local symptoms of suppuration, this area should be selected as the object of the surgical attack. If not the precise situation of the disease, it will in most instances serve as a guide to the purulent collection. Exploratory aspiration is objected to as a measure of diagnosis. It will not show whether the cavity be a large or a small one, and is a very probable source of danger in cases in which the affected portion of lung is not adherent to the wall of the chest. The author, in concluding his paper, describes his method of treating pulmonary abscesses, which consists in resection of portions of one or more ribs, free exposure of the parietal layer of pleura, and in making with the thermo-cautery a free opening into the cavity after he has assured himself that adhesions exist between the lung and parietal pleura, or by a prolonged application of caustic has artificially established such adhesions. Pleural adhesions at the seat of operations he regards as an imperative condition in pneumonotomy. If there be any doubt as to the existence of such adhesions the surgeon must act upon the assumption that they are absent.

Acute Nephritis from Oxalic-Acid Poisoning.—

At a late meeting of the Pathological Society of London (*The Lancet*), Dr. Hale White brought forward two cases of "Acute Nephritis due to Oxalic-Acid Poisoning." The first was fatal, apparently from uræmia, six days after the acid had been swallowed. The necropsy revealed acute tubal nephritis, with several minute masses of oxalic crystals in the kidney only visible with a high power. Neither patient showed any œdema, high-tension pulse, or hæmaturia, nor did they complain of pain in the loins, although this might have been obscured by the general abdominal pain. The symptoms appeared, judging from these two cases, to be scanty urine—the fatal case had almost complete suppression—and albuminuria. The urine contained granular and epithelial casts, together with calcium oxalate crystals. Both the crystals and the albumin were found in both cases in the first specimen of urine passed after the acid had been swallowed. In the case which recovered the crystals disappeared from the urine in twenty-four hours, the albumin persisted four days and the casts about a week. The quantity of urine gradually increased until on the fifth, sixth, seventh, and eighth days from swallowing the acid much more than normal was passed, and it was pale and of low specific gravity. Seven days after taking the poison this patient passed a quantity of phosphates in his urine, and after this he often passed a considerable

quantity of uric acid. In the fatal case the oxalate crystals and the albumin remained in the urine till the end, and the amount of urine passed in twenty-four hours varied between a drachm and four ounces.

Cancer of the Cervix Uteri.—Dr. Cordier (*International Journal of Surgery*, June, 1896, p. 158) draws the following deductions: 1. Cancer of the cervix uteri, if left without surgical interference, always kills. 2. The disease, in most instances, is, primarily, a local process. 3. Early hysterectomy will cure quite a percentage of these cases. 4. The microscope, while a great diagnostic assistant, is not infallible in its findings. 5. The experienced surgeon is warranted in resorting to a hysterectomy, even in the doubtful cases. 6. All malignant pregnant uteri should be removed when seen before the disease has advanced beyond the period of a probable cure.

The Tonsillar Cough.—According to Dr. Furet, this cough may result from any pathological alteration of the tonsils. It was sufficiently explained by the complex innervation of the gland. In fact, the glossopharyngeal, the lingual, the spinal, and the pneumogastric nerves were blended and became entangled at their outer surface, where they formed a small plexus, which Andersch had described under the name of the tonsillar plexus. It must not be forgotten that the tonsils were inclosed by the muscles of the pillars of the fauces, which were very distinctly connected with the muscular apparatus of the larynx. Tonsillar cough was violent, spasmodic, and even extremely painful. It was frequently accompanied by reflexes in the neighboring region, and particularly by watering of the eyes. It was distinguished from the cough due to affections of the respiratory tract by the complete absence of expectoration, and, owing to this fact, it did not yield to any of the remedies generally used.—*La Presse Médicale*.

Results of the Bacteriological Examination of One Thousand Cases of Suspected Diphtheria.—

Drs. Hewlett and Nolan publish a review of results of the bacteriological examination of specimens from one thousand consecutive cases of suspected diphtheria, forwarded by medical officers of health and practitioners from all parts of the kingdom to the institute for diagnosis. In five hundred and eighty-seven cases the diphtheria bacillus was found, in four hundred and nine cases it was not found, and in four instances there was doubt as to its presence. Two specimens were from cases of conjunctivitis: in one the diphtheria bacillus was found; in the other, which was associated with faucial diphtheria, only the streptococcus pyogenes. In one instance specimens were taken from the fauces and from the vagina of the same case, and bacilli were found in each. In another, a pure culture of the diphtheria bacillus was obtained from a severe case in which the infection of the throat probably originated from a diphtheritic wound of the finger incurred during laboratory work. Examinations were also made to determine the time of disappearance of the bacilli from the throat. This was found by them, as it had been by former observers, to be exceedingly variable. The bacilli were commonly found for two or three weeks; in one instance they remained for seven weeks, in another for nine weeks, and in another for twenty-three weeks. In the latter case they remained virulent for guinea-pigs. In conclusion, the authors insist upon the desirability of a bacteriological examination in all cases in which the throat symptoms are at all doubtful, as many of their cases which were not regarded clinically as diphtheria proved to be such. They also emphasize the necessity of repeated examinations after convalescence, with isolation, until the absence of the infective agent has been shown.—*British Medical Journal*.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, July 25, 1896.

DIPLOMA MILLS AND STATE PROTECTION.

IN spite of the strenuous efforts of all honest men interested in the advancement of medical qualifications and in the face of laudable endeavors in enacting suitable laws to such an end, it is quite discouraging to notice that the State of Wisconsin in particular comes boldly to the front as an open abettor of fraud and by the sanction of authority offers a direct encouragement for the free and shameful sale of medical degrees. The profession of that State owes it to itself, to common decency and fair play, to everything that is right and honest, to see to it that such a traffic shall be duly exposed and promptly stopped. Whatever may have been the intention of the framers of the law at present in force in Wisconsin, it is quite evident from the following correspondence, kindly forwarded by one of our readers, that the literal construction of the provisions of the act makes possible the most outrageous abuse of statutory provisions:

"Always give your Full Address every time you write, no matter how often it may be."

"FRED. RUTLAND, M.D., *Pres.*; A. NEVE RUTLAND, M.D., *Sec.*; JULES GORDON, M.D., *Treas.*

"Incorporated under the Law of the State of Wisconsin.

"WISCONSIN ECLECTIC MEDICAL COLLEGE,

"OF MILWAUKEE, WIS.

"CORRESPONDENCE DEPARTMENT,

"1001 WEST CONGRESS ST.,

"CHICAGO, ILL., July, 1896."

"DEAR DOCTOR: We notice your name in a Medical and Surgical Directory, but with a * appended. This usually means (although not necessarily so) that the person so designated is not a graduate of a medical school, and has no diploma. If, however, it should be that you are a graduate, and have a regular diploma, then we can but tender our most sincere apologies for troubling you on the matter. But, on the other hand, if you are not a graduate, and have no regular diploma, then the perusal of the enclosed prospectus cannot fail to be of the most primary importance and interest to you. We would also desire to draw attention to the fact that to practising physicians our fees are much reduced from the regular rate. To this class our fees are \$35, all inclusive.

"As proof of our legal standing and right to confer the degree of M.D. we can supply certified copies of

our charter at 25 cents each, simply covering the cost of certifying officer's fee.

"Trusting soon to hear from you and standing ready to answer any or all questions you may wish to submit,

"We are, yours very sincerely,

"WISCONSIN ECLECTIC MEDICAL COLLEGE,

"Fred. Rutland, M.D., *President.*"

Accompanying this letter is the following circular:

"This is a True Copy of the Charter of Our College.

"UNITED STATES OF AMERICA.

"THE STATE OF WISCONSIN,

"DEPARTMENT OF STATE.

"To All to Whom these Presents shall come:

"I, Henry Casson, Secretary of State of the State of Wisconsin, do hereby certify that there has been this day filed in this department an instrument in writing, purporting to be Articles of Association, with a view of forming a corporation to be known as

"Wisconsin Eclectic Medical College,

"at Milwaukee,

without Capital Stock, the business and purpose of which shall be to conduct a Medical College, etc., and verified as a true copy by the affidavit of Fred. Rutland, M.D., and Ann Neve Rutland, M.D., who appear in said instrument as two of the signers of said articles; theretore the State of Wisconsin does hereby grant unto the said

"Wisconsin Eclectic Medical College,

"at Milwaukee,

the powers and privileges conferred by Chapter 86 of the Revised Statutes of the State of Wisconsin and all acts amendatory thereto, for the purposes above stated and in accordance with their said Articles of Association.

"In Witness Whereof, I have hereunto set my hand and affixed my official seal, at the Capitol in the City of Madison, the thirty-first day of December, in the year of our Lord one thousand eight hundred and ninety-five.

"HENRY CASSON,

[Seal.]

"Secretary of State."

These are the plain facts in the case and can speak for themselves. The college in question, judging from the print in the circular letter, is situated in one corner of the upper story of a business block and evidently has abundance of room for a correspondence department.

The prospectus to which reference is made in the personal letter takes it for granted that there are great numbers of deserving students who cannot practise medicine because they have not means enough to attend high-class colleges, and therefore that the college in question will make it easy for such aspirants who in its estimation should have legitimate privileges for obtaining a living, in spite of the oppressive and unjust laws in other States. To such as have, "owing to the medical laws, practised medicine illegally the Wisconsin Eclectic Medical College comes as a boon and a blessing." Again, "it is possible for students to graduate without attendance." It is apparently sufficient to "arrange for their examination before a notary public of their town and if the examiners of

this college can be satisfied they can be legally and lawfully graduated, receiving the diploma of the college conferring the degree of doctor of medicine without attendance at the college." Of course an examination appears to be requisite, but where is the guarantee that the conditions requiring it will ever be fulfilled or ever be anything more than the merest pretext for a graduation fee? The object of this missionary work is too transparent for explanation or discussion. What can we think of any State legislature that could make such doings possible? What will eventually be the standard of medicine in Wisconsin when it can be lowered to such a level? Surely our good brethren of the Wisconsin State Society should take this matter in hand, promptly and with a becoming seriousness of purpose.

IS PULMONARY CONSUMPTION A FACTOR FOR THE ELIMINATION OF THE UNFIT?

DR. THOMAS J. MAYS, of Philadelphia, in the discussion of this question calls attention to the fact that in addition to the inherited tendency to pulmonary disease, nervous diseases—such as insanity, idiocy, hysteria, chorea, epilepsy, and asthenia—may be translated into pulmonary consumption between parents and children, and that the latter may be convertible into the former in the same way. Dr. G. Fielding Blandford says: "I have found phthisis and insanity frequently coexisting in the same family." Dr. Stearns says: "We often see a consumptive having a child which, instead of developing consumption, develops insanity, and *vice versa*." Dr. Clouston makes the observation that the death rate from pulmonary consumption among the insane is four times greater than it is among the general population, and both diseases are very common among different members of the same family, and that heredity toward consumption may determine insanity and heredity toward the latter may produce the former. The forms of insanity commonly associated with phthisis are monomania of suspicion and melancholia. Dr. Mays says that there is a similar prevalence of consumption in families burdened with idiotic children. The influence of heredity in transforming nervous diseases into pulmonary consumption and the reverse is so obvious that even lay writers have observed it.

The poisons of influenza and of whooping-cough, and alcohol, lead, and mercury are powerful exciting causes of pulmonary consumption. In fact, any influence which depresses or disintegrates the brain and nervous system may prove an exciting cause of pulmonary consumption. Dr. Mays states that the above facts would seem to brand the consumptive as a degenerate and unfit to survive the struggle for existence; but he goes on to show that the nature of many of these stricken with this disease stamps them as beings of the highest order of beauty and intelligence. Dr. Churchill says that the connection between acute sensibility and phthisis is so striking that poets of all times and all countries have employed their most touching accents to deplore the premature fate of some of those victims

to consumption whose youth was bright with promise of future excellence and distinction. The author says that high intelligence and physical beauty belong to a certain type of phthisical temperament and that, in all probability, both are the outcome of a refined nervous organization, delicate by reason of the exalted place it has obtained in the process of evolution, more easily unbalanced by unfriendly influences, and consequently less fit to undergo the severe and exhaustive struggles which are necessary in the present imperfect state of our civilization. More people succumb to phthisis and insanity between the ages of twenty and thirty than at any other time of life, which fact would seem to conform to the above statement.

The author concludes as follows: "Facts, therefore, fail to confirm the belief that pulmonary consumption is designed to purge society of the unfit; on the contrary, sufficient reason has been given to show that many of those who fall victims to this disease are drawn from a class of society which represents the most progressive type of human development."

Has the author actually proved that the consumptive is not eliminated as unfit? The fact that he succumbs is evident proof that he cannot sustain the struggle for existence under present conditions. His faculties may be brilliant, but he is in an unstable condition in that his physical development has not kept pace with his nervous and mental evolution. In barbaric ages, war, famine, and disease were regarded as a means of disposing of surplus population, but the economist tells us there need be no fear of overpopulation, as three-fourths of the products of the earth go to waste annually. The altruistic feeling that now prevails abhors the idea that nature should employ disease as a means of elimination. It seems more reasonable to regard it rather as an accident of the human race, a misfortune which science can in time rectify. Dr. Mays gives statistics to show that pulmonary consumption is on the decrease, and says the reduction is due to better food, better clothing and shelter, better homes, better physical and mental training, better sanitation, and elevation of the moral standard. It is to be regretted that in addition to these means, that hold so much promise to future generations, we cannot have laws preventing the marriage of consumptives, that those to whom the moral side of the question would not appeal might still be controlled. It is also to be regretted that the many suffering from this disease seem doomed, and that medical science holds out so little prospect of immediate relief; but we have evidence that we are slowly progressing, and science may yet find the means of wiping out pulmonary consumption as effectually as it has small-pox.

A Dumb Thermometer.—A member of the Zurich Medical Society recently exhibited a self-registering clinical thermometer on which there were no degree marks. The instrument could be left with the patient's family to take the temperature in the absence of the physician, and the latter could then read it by means of an attachable scale of glass or metal.

News of the Week.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the Medical Corps of the United States Navy for the week ending July 18, 1896: July 14.—Surgeon R. C. Persons, orders to duty at naval hospital revoked and ordered to continue on present duty; Passed Assistant Surgeon H. N. T. Harris, ordered to the Pensacola navy yard. July 15.—Surgeon S. H. Dickson, ordered to the *Texas*; Assistant Surgeon J. M. Moore, detached from naval hospital, Norfolk, and ordered to the *Texas*. July 17.—Assistant Surgeon A. Farenholt, detached from the *Monterey* and ordered to the Mare Island hospital, California.

Anti-Vivisection Legislation.—The following preamble and resolutions were passed by the American Surgical Association at its session in Detroit, May 27, 1896:

"Whereas,

"(1) The American Surgical Association has learned that the committee on the District of Columbia in Congress has reported favorably a bill adverse to the practice of vivisection in the District of Columbia, and

"(2) The passage of such a law will put an end to all the experimental work in the governmental laboratories at Washington from which have emanated important and useful discoveries, especially as to the diseases of animals, and

"(3) The passage of such a law by Congress will be used as a lever in promoting the enactment of similar laws in other parts of the country and so do double harm;

"Therefore, *Resolved*, by the American Surgical Association,

"(1) That to their personal knowledge the marvelous progress of surgery, especially within the last twenty-five years, is due very largely to experiments upon animals, and the continuance of such experiments is absolutely essential to the further progress of surgical science.

"(2) That in their opinion the humanity of the entire profession is too well known and too constantly and conspicuously shown in their enormous charitable and kindly work to allow the assertion that they would countenance the practice of cruelty or the infliction of needless pain in such experiments to be believed by the American people or their representatives in Congress.

"(3) By reason of this very humane sentiment, this Association protests against the passage of the bill in question, because it will be a cause of untold cruelty to both man and animals by arresting to a great extent the beneficent progress of surgery.

"(4) That a copy of these resolutions be sent to the President of the United States and to the Senate and House of Representatives.

"W. W. KEEN, H. L. BURRELL, JOSEPH D. BRYANT, committee."

Jefferson Medical College Hospital.—Eckley Brin-

ton Coxe, Jr., has contributed \$5,000 for the endowment of a free bed in the contemplated new Jefferson Hospital.

The Spanish Soldiers in Cuba.—During the last third of June there were about 8,000 men lying ill in the Spanish military hospitals in Cuba, of which number 1,300 were suffering from yellow fever. The mortality rate of this disease is increasing. The epidemic of small-pox shows no signs of diminishing.

Dr. Frank Whitman Ring, of this city, died on July 17th, in New Haven, from disease of the heart. He was born in Portland, Me., forty-eight years ago, and studied medicine in Bowdoin College, where he received his degree in 1878. He came to New York to practise in 1879, and soon became associated with the Manhattan Eye and Ear Hospital, retaining his connection with this institution up to the time of his death. He was a member of several medical societies of this city, and was the author of a number of papers on subjects relating to his specialty. He had two brothers who are physicians, and he leaves a widow to whom he was married but a few months ago.

Obituary Notes.—DR. WILLIAM H. MATLACK died at Downingtown, Pa., on July 12th, at the age of 59 years. He had been a paralytic for many years, but as one time was a prominent practitioner and an active politician.—DR. CHARLES DE COSTA BROWN died in New York City on July 12th, at the age of 79 years. He was a native of Philadelphia and was graduated from the University of Pennsylvania. He practised medicine for a time, but subsequently engaged in the practice of dentistry. During the war he acted as government embalmer. He was a prominent member of the Masonic fraternity.—DR. FRIEDRICH AUGUST KÉKULÉ, professor of chemistry and first examiner in pharmacology at the University of Bonn, died on July 16th.—DR. E. B. STEVENS, of Lebanon, O., died at his residence, July 11th, in his seventy-third year. For seventeen years he edited the *Cincinnati Lancet and Observer*, now the *Lancet-Clinic*, and afterward conducted the *Obstetric Gazette*. He was professor of materia medica and therapeutics in the Miami Medical College from 1865 to 1873, and in the University of Syracuse from 1872 to 1877.

Arsenic in Cigarettes.—Dr. William Murrell publishes in the *British Medical Journal* of July 11, 1896, a preliminary report of an analysis which he has made of the paper wrappings of smoking tobacco and cigarettes. He found that of seventeen samples of tobacco and cigarette packages arsenic was present in the labels of six. The presence of arsenic in the wrappers of cigarettes, he thinks, must be attended with considerable risk to the smoker, for the coloring matter easily rubs off on to the fingers, especially when moist, and from the fingers on to the cigarettes. Most packet tobaccos are put up by machinery, but the papers are spread by girls, who must of necessity in the course of their work absorb a good deal of arsenic. The danger is both to the consumer and to those engaged in the manufacture of cigarettes. The presence of arsenic is by no means confined to the cheaper brands,

for it occurs abundantly in many of the high-priced packet cigarettes. The rice papers, which form the wrappers for the cigarettes, and the tobacco itself have been examined by Dr. Murrell, but the experiments are not yet sufficiently advanced to permit the formulation of positive conclusions.

The Cholera in Egypt.—During the first half of July, 5,441 cases of cholera with 4,602 deaths were reported in Egypt. The unusually large percentage of deaths is doubtless to be explained by the fact that most of the cases that recover are not reported, and it is probable that the number of cases was much nearer 9,000 than 5,000. In the Soudan there were 269 cases with 165 deaths on July 18th among the Egyptian and English troops.

War Dogs and the Wounded.—A special feature in this year's German manœuvres, says a writer in *La France Militaire*, will be supplied by war dogs which have been most admirably trained for seeking the wounded and carrying dispatches. At the command "seek," accompanied by a gesture indicating the direction in which the dogs are to search, they will start off without allowing themselves to be disturbed by any surrounding circumstances; they will find the men who figure as wounded with unfailing certainty, take a piece of their clothing—cap, helmet, or piece of cloth torn off, and bring this back to the ambulance men, whom they then conduct to the spot.

Wholesale Prosthesis.—The Italian government recently sent an artificial-limb maker to Africa to supply hands and feet to about two hundred and fifty native soldiers who had been captured by the Abyssinians and, after having each a foot and a hand cut off, were set free again.

The Third International Psychological Congress will be held at Munich, Bavaria, from the 4th to the 7th of August, in the halls of the university. The work of the congress will be distributed through five sections: (1) The physical basis of psychical phenomena, the anatomy of the brain, and the province of psycho-physics in general. (2) Phenomena of consciousness in the strict sense of the term, psychology of the normal individual, including laws of association, activity of the imagination, doctrines of the emotions and of the will, the evolution of the personality, facts of ethics, etc. (3) Psycho-pathology, genius and insanity, illusions of the senses, fixed ideas, suggestion, psychology and criminology. (4) Psychology of sleep, dreaming, hypnotism in its application to the healing art, telepathy, mind reading, etc. (5) Comparative psychology, mental capacities, and moral conceptions of the lower races of mankind, graphology, the relation of psychology to pedagogy, the instruction of backward children through suggestion, and kindred topics.

A Field for the Energy of Anti-Vivisectionists.—Attention has been called in the *London Times* to the feather ornaments of women's hats, and especially to those from the osprey. In order to obtain these the parent birds are killed during the breeding-season and their young are left to starve to death. This agitation

has, however, had little effect, and the feathers continue to be worn by many women who are doubtless moved to tears at the thought of the cruelty practised by physiologists in their experiments. But, as the *British Medical Journal* well says, "more suffering is produced to supply the bonnets for one garden party than in all the physiological laboratories of the world."

The Jenner Centenary in Japan was held in Tokio on May 14th, the occasion being one of great solemnity. There were many speakers, including the president of the House of Peers, the minister of education, the surgeon-in-chief of the army, Count Hijikata, and the British minister to Japan. Many Japanese notables and the members of the diplomatic corps were present.

The British Medical Association will hold its sixty-fourth annual meeting at Carlisle on Tuesday, Wednesday, Thursday, and Friday, July 28, 29, 30, and 31, 1896. The president-elect is Dr. Henry Barnes, physician to the Cumberland Infirmary, Carlisle. The address in medicine will be delivered by Sir Dyce Duckworth, lecturer on medicine, St. Bartholomew's Hospital; that in surgery will be delivered by Dr. Roderick Maclaren, senior surgeon to the Cumberland Infirmary. The scientific business of the meeting will be conducted in nine sections.

Hebrew Medical Men at the Moscow Congress.—It is stated in the St. Petersburg *Viedomosti* that the Russian minister of the interior has decided to permit the entry into Russia of foreign Jews without distinction of calling. Such persons, however, must be provided with passports bearing the visé of a Russian consul, who shall have previously received the requisite authority from the Russian minister of the interior. The announced intention of Virchow to resign his post as president of the German committee for the International Medical Congress, unless the Russian government altered the passport regulations in favor of the Jewish members of the medical profession who will visit Moscow from Germany, has probably had something to do with this action of the Russian minister. The present law practically prohibits the entrance into Russia of any Hebrew, whatever may be his occupation or the business which takes him to that country.

Homœopathic Representation on the Medical Staff of a Hospital.—A committee of the board of managers of the Chester (Pa.) Hospital has reported favorably upon a petition of homœopathic practitioners for representation upon the medical staff of the hospital.

The Center County (Pa.) Medical Society, at its session at Bellefonte on July 14th, listened to papers on "Gastro-Intestinal Antisepsis," by Dr. W. B. Henderson, of Philipsburg; on "Post-partum Hemorrhage," by Dr. George F. Harris, of Bellefonte; on "Typhoid Fever," by Dr. E. A. Russell, of Unionville.

Dr. Samuel Wilks, president of the Royal College of Physicians, has been appointed one of the physicians extraordinary to the Queen, in place of the late Sir George Johnson.

Reviews and Notices.

MEDICAL JURISPRUDENCE, FORENSIC MEDICINE, AND TOXICOLOGY. By R. A. WITTHAUS, A.M., M.D., and TRACY C. BECKER, A.B., LL.B., and Collaborators. Volume III. New York: Wm. Wood & Co., Publishers.

THIS is the third of the four volumes which this treatise comprises. The two previous volumes have already been noticed in these columns. The present volume is made up of the following-named articles: "Vision and Audition in Their Medico-Legal Relations," by Dr. J. H. Woodward; "The Medico-Legal Aspects of Insurance," by D. Murray and G. J. Edmonds; "Insanity in its Relations to Medical Jurisprudence," by Dr. E. D. Fisher; "Mental Unsoundness in its Legal Relations," by T. C. Becker; "Care and Custody of Incompetent Persons," by Goodwin Brown, and a table of cases cited in the volume.

The chapters by Dr. Woodward are carefully prepared, although the discussion of many of the subjects embodied is by no means exhaustive. In some instances, such as in the chapter on simulated blindness, the preponderance of quoted matter is striking. The visual shortcomings associated with and dependent upon traumatic neuroses and hysteria are inadequately considered. On the other hand, the chapters which embrace the traumatic affections of the eye and its environs are handled more skilfully and satisfactorily. Relatively inadequate space is given to audition as compared with that given to vision, fifteen pages to the former, one hundred and ten to the latter. In the dissociation of nerve impulses following injury in hysteria, in malingering, conditions which are continually being worked over in courts of law, much information of value can be obtained by examination of the auditory apparatus; and although Dr. Woodward does not attempt to treat any affections of the ear except those due to injury, we believe a brief consideration of these subjects would not have been amiss, even if consideration had been given them under another caption.

The medico-legal aspect of insurance is considered by Mr. D. Murray, of the Equitable Life Assurance Society, and G. J. Edmonds, Esq., of the New York bar.

The manner in which the matter is presented, as well as the way in which the subject is conceived, are both deserving of the highest praise. There is no obscuration of facts by words, no tedious citation of matter that is not directly pertinent.

The most pretentious article in the volume is by Dr. E. D. Fisher, whose contribution covers about two hundred pages. The writer has contributed to his reputation as an alienist and to medico-legal knowledge. Dr. Fisher follows Krafft-Ebing in both classification and definition with the closeness of a genuine disciple. If space permitted the extensive consideration of this article, such as it deserves, it would be necessary to point out, here and there, positions assumed by the author which we do not think are shown to be tenable, either by virtue of such assumption or by any arguments advanced. For instance, impulsive insanity is said to be a mental state similar to those which he has just previously been considering with moral insanity, hallucinatory mania, dementia with apathy, etc. Nor do we see the necessity of considering the opium habit as a mania, for psychical exaltation, the *sine qua non* of mania, is not a part of it.

Amittoris paranoia is a most unfortunate designation to indicate what is desired to be conveyed by the term paranoia reformatoria. In discussing paranoia Dr. Fisher differs very radically from other writers, particularly in his statement that paranoia is rare in any form before puberty, as most authorities, such as Krafft-Ebing, Krapelin, Werner, *et al.*, believe that one great class of paranoias, *i.e.*, those presenting the rudimentary form of paranoia, is present before puberty.

The various forms of insanity are taken up by the author and illustrated in many instances by typical cases related by word and picture. The mental perversions attending on alcohol and epilepsy are particularly noteworthy.

In one particular we must take serious exception to Dr. Fisher's teachings, and that is concerning aphasia. He says "aphasia may be simply motor, in which there is difficulty to express the ideas desired by reason of impaired articulation, or there may also be a loss of the names of things, *i.e.*, amnesic aphasia, so that communication has to be carried on by gesture." In the first place, communication is never carried on by gesture, for gesture is not the product of

cognition, but is an external expression of feeling strictly analogous to an oath, and is very similar to if not quite a reflex act. Communication may, however, be carried on by pantomime, but this may also be destroyed in motor aphasia, the condition constituting what is known as amimia. So that the inference which the sentence quoted would give, *viz.*, that in motor aphasia communication of percepts and concepts can still be made in some way, is a decidedly erroneous one. The importance of this matter is brought home to one most emphatically if he be called upon to affirm or deny the testamentary capacity of one with motor aphasia. And most emphatically do we deny that an extreme degree of dementia is always present with mind blindness, in which apraxia, or loss of the faculty to use things properly, is present. It would be just as tenable to hold that there is necessarily dementia in those cases in which the percept of words is lost.

Next to Dr. Fisher's article is one on the legal relations of mental unsoundness by Mr. Becker, which naturally follows on the discussion of insanity from the physician's point of view. So far as we are capable of judging, this is a lucid exposition of what it purports to consider. The second part, on criminal responsibility, has been done with the aid of Dr. Fisher.

Mr. Goodwin Brown, who as State lunacy commissioner has had opportunity to make himself familiar with the custodianship of insane persons in the State, writes a most useful and exhaustive article on the care of incompetent persons and their estates. As a reference work for the practising physician, this contribution is invaluable. It not only gives a careful consideration of the processes of inquisition and supersedeas, and intructions as to committees and guardians, management of estates, etc., but an exhaustive digest and *résumé* of the statutes of all the States. The latter must be of great service to every examiner in lunacy, as well as to physicians and lawyers generally.

The volume as a whole is abreast of its predecessors. In some respects it is in advance. If the succeeding volume maintains the standard of merit of those that have gone before it, we shall be able to say that at last we have a system of medical jurisprudence worthy of highest commendation.

DIRECTIONS FOR WORK IN THE HISTOLOGICAL LABORATORY. By DR. G. CARL HUBER, Assistant Professor of Histology and Embryology in the University of Michigan. Ann Arbor: George Wahr, Publisher.

THIS little volume of 175 pages, half of which are left blank for drawings, consists of twenty-five lessons more especially arranged for classes in the University of Michigan. The directions are explicit, sufficiently comprehensive, and the little work fulfils what it purports to do. The lessons on examination of the blood are least satisfactory.

SCIENCE PROGRESS; A MONTHLY REVIEW OF CURRENT SCIENTIFIC INVESTIGATION.

THE February number of this magazine contains among other contributions a highly interesting article on emancipation from scientific materialism, by Professor Ostwald, of the University of Leipzig, the continuation of a suggestive article on the space relations of atoms, by Dr. A. Eiloart, formerly of the New York Post-Graduate School, and a decidedly valuable article on the suprarenal capsules, by Dr. Halliburton, professor of physiology in King's College, London. This number maintains the commendable scientific standard set by its editors.

TRAITÉ DE CHIRURGIE CÉRÉBRALE. Par A. BROCA, Chirurgien des Hôpitaux de Paris, Professeur Agrégé à la Faculté de Médecine, Membre de la Société de Chirurgie, et P. MAUBRAC, Ancien Prosecteur à la Faculté de Médecine de Bordeaux.

TREATISE ON CEREBRAL SURGERY. By PROF. A. BROCA and DR. P. MAUBRAC.

THE increasing interest in brain surgery is shown not only by the numerous articles upon this subject which appear in the medical journals, but also by the publication of monographs and formal treatises, of which the present one is the latest. Professor Broca has been known as one of the few surgeons in France who has taken an active interest in this subject, and the record of his operations in this book numbers thirty-one. The work opens with a chapter on the anatomy of the convolutions of the brain, which is followed by a chapter upon the topography of the various functional areas as re-

lated to the skull. These chapters are very carefully prepared, and give a *résumé* of all the various methods proposed for determining the relations between the surface of the head and the convolutions of the brain. The third chapter presents in clear form the facts of localization upon which are based the diagnosis of local lesions, and this is followed by a chapter upon the operative technique and its dangers. The authors seem to prefer the trephine to the chisel in opening the skull.

The second part of the book is devoted to a study of the various diseases in which operative interference is warranted. These are taken up in the following order: the traumatic lesions, primary and secondary; the intracranial complications of otitis media; meningitis; phlebitis of the sinuses and abscess; intracranial tumors; hemorrhage and meningitis; hydrocephalus, microcephalus; various functional troubles, including epilepsy, psychoses, and headache; encephalocele. Each of these subjects is discussed with great care and thoroughness, and all the facts at present accessible are put clearly before the reader.

The book is to be especially commended for its full references to modern literature, including both English and American authors, who are usually entirely neglected by the French writers. The references alone demonstrate how much more interest has been taken in cerebral surgery in England and America than on the continent of Europe. It is to be hoped that this work, like that of Chipault, will succeed in convincing our continental confrères of the utility of this form of surgical interference. The standpoint of the authors is not optimistic, and yet the propriety of surgical interference in certain cases of brain disease is forcibly presented. The work can be highly commended, as it is a reliable presentation of the facts up to date.

A MANUAL OF MEDICAL JURISPRUDENCE AND TOXICOLOGY. By HENRY C. CHAPMAN, M.D. With 55 illustrations and 3 plates in colors. Philadelphia: W. B. Saunders. 1896.

THIS little volume has reached a second edition in three years. With the exception of a brief bibliography, the present edition is the same as the first. The contents of the volume are divided into two parts, the first being devoted to medical jurisprudence, the second to toxicology. In the first part the chapters devoted to the signs of death and the examination of blood stains are particularly lucid and helpful, considering the short space which the author has given himself for their discussion. The chapters on rape, signs of pregnancy, fœticide, and infanticide contain nothing new, they reflect with accuracy the universal teachings on these subjects. The chapter on feigned bodily disease, hypnotism, etc., is incomplete and does not add materially to the knowledge of these subjects. The two chapters devoted to toxicology are the embodiment of discriminate and careful statement.

SYPHILIS IN THE MIDDLE AGES AND IN MODERN TIMES. By DR. F. BURET. Translated by DR. A. H. OHMANN-DUMESNIL. Philadelphia: The F. A. Davis Company. 1896.

THIS is the second part of Buret's well-known historical work. It consists of two volumes, the first dealing with syphilis in the Middle Ages, the other with syphilis in modern times. The first chapters of Volume I. are taken up with a discussion of syphilis in Europe in the first fifteen centuries of our era, while the last discusses the pretended American origin of the syphilitic virus. Buret's pronounced views on this question are too well known to need repetition; a simple examination of facts shows how fragile was the evidence on which the supposition of the American origin of syphilis was made. The little volume is well translated and is a handy work of reference.

DAME FORTUNE SMILED: THE DOCTOR'S STORY. By WILLIS BARNES. Boston: Arena Publishing Company. 1896.

"Dame Fortune smiled,
And never did a dame smile more."

It may be a true story and it may have happened to the author's hero, but such luck never came to any mortal doctor before, nor will it come again.

Such a work is simply an irritation to a struggling practitioner, thinking where his next small fee is to come from.

German medical students may be attracted to this country by the glowing, glittering accounts of the string of financial and other good fortunes which overtook this adventurer abroad. May they bear their disappointments with the same fortitude as Mr. Barnes' hero displays in bearing his fortunes. As a novel of absorbing interest, not much can be said in its favor.

CLINICAL LECTURES ON ABDOMINAL SURGERY AND OTHER SUBJECTS. By CHARLES T. PARKES, A.M., M.D., Late Professor of Surgery, Rush Medical College, Surgeon to the Presbyterian Hospital, Surgeon in Charge of St. Joseph's Hospital, Surgeon in Chief of Augustana Hospital, Consulting Surgeon of the Hospital for Women and Children, etc. Edited by DR. A. J. OCHSNER. Chicago: The W. T. Keener Company. 1896.

THESE lectures have been prepared for publication and edited by a former pupil and clinical assistant of the late Dr. Parkes. They are reproduced from the stenographic notes taken during the past few years; the form of language in which the original lectures were delivered being retained, thus lending an especial force and charm to the work for all those who were formerly students and friends of the author.

Chapter I. deals with abdominal tumors. Chapter II., gun-shot wounds of the stomach and of the small intestines, including numerous experiments upon dogs, and gun-shot wounds of the abdomen. Chapter III. is upon renal calculus and surgery of the kidney. Chapter IV. includes tuberculosis, malignant growths, hernia, tumors, fractures, and many other subjects of minor surgery.

The work is not systematized, nor does it have the finish we might have expected had the author personally prepared and supervised the sheets for publication.

Some of the chapters contain matter which has already appeared as contributions to scientific societies.

DEAF-MUTISM. A CLINICAL AND PATHOLOGICAL STUDY. By JAMES KERR LOVE, M.D., Aural Surgeon to the Glasgow Royal Infirmary, Honorary Aurist to the Glasgow Deaf and Dumb Institution. With Chapters on the Education and Training of Deaf-Mutes, by W. H. ADDISON, Principal of the Glasgow Deaf and Dumb Institution. Pp. 369. Published by James MacLehose & Sons. Glasgow. 1896.

THE writer treats the subject exhaustively and scientifically. He considers deaf-mutism in general, the character of deaf-mutes, congenital and acquired deaf-mutism, the defects and maladies of the ears. He takes issue with Hartmann and Toynbee in the matter of total deafness of deaf-mutes. These writers found most of their patients totally deaf, while he believes that total deafness is not common among them. The chapter on congenital deafness, which deals with its relation to heredity and consanguineous marriages, claims the thoughtful attention of the reader. He says that in calculating the chances of deafness in offspring the family antecedents of both sides as well as of the father and the mother should be considered. Much has been written on the relation between consanguineous marriages and deaf-mutism, and the author reviews the literature on this subject in an instructive manner.

He says that the study of census returns shows that there is a steady stream of deaf-mutism, flowing through decade after decade in spite of all efforts to check it. It should be combated by all means which can prevent deafness following disease, and by the discouraging of marriage between those afflicted and those near akin.

The chapters on "Education of Deaf-Mutes" will be of special value to those whose work is in this direction.

TEXT-BOOK OF GENERAL PATHOLOGY AND PATHOLOGICAL ANATOMY. By RICHARD THOMA, Professor of General Pathology and Pathological Anatomy in the University of Dorpat. Translated by ALEXANDER BRUCE, M.A., M.D., F.R.C.P.E., F.R.C.S.E. Vol. I., with 436 illustrations. London: Adam and Charles Black. 1896.

THIS work, though entitled a text-book, is far from elementary. The physician as well as the student will read with interest and profit the result of Professor Thoma's researches in the ever widening domain of pathology. The chapters vary in interest and importance, showing an inequality in the presentation of various subjects. The chapter on infec-

tions and parasites, which includes the recent researches in micro-organisms, is full and interesting and brings the subject up to date. The chapter on malformations, including monstrosities and other embryonic deformities, is especially elaborate and will be consulted as a valuable reference on that subject. The chapter on tumors is disappointing. The copious illustrations are finely done and contribute markedly to the success of the volume.

The translator is to be congratulated upon the thorough and conscientious manner in which he has performed his difficult task.

A TEXT-BOOK OF BACTERIOLOGY. By GEORGE M. STERNBERG, M.D., LL.D., Surgeon-General, U. S. Army; Ex-President American Public Health Association; Honorary Member of the Epidemiological Society of London, of the Royal Academy of Medicine of Rome, of the Academy of Medicine of Rio de Janeiro, of the Société Française d'Hygiène, etc., etc. Illustrated by Heliotype and Chromo-Lithographic Plates and Two Hundred Engravings. New York: William Wood and Company, 1896.

THOSE who are acquainted with the author's "Manual of Bacteriology," published a few years ago, and which won for itself at once the position of an acknowledged authority in this comparatively recent science, need no description of the present work. It is based upon the Manual, but is of smaller proportions, the description of non-pathogenic bacteria and the bibliography contained in the larger work being here omitted in the endeavor to bring the book within the compass of one suited to the needs of the general practitioner and the student. But to one who has not seen the Manual this description is most inadequate. In the first place a comparison of the two works shows that the later one is far from being a simple condensation or a reprint of certain portions of the former one. The science of bacteriology is constantly progressing, but the author has kept abreast of it and has embodied all the advances of the past three years in the "Text-Book," which in this respect might be regarded as supplementary to the "Manual."

The first part deals with classification, morphology, and general bacteriological technology; in the second the general biological characters of bacteria are considered; the third section, occupying about half of the work, is devoted to a description of the pathogenic bacteria; and in the fourth part the saprophytes are briefly described. The book is well written in the author's lucid and pleasing style, and the illustrations leave nothing to be desired in point of execution and of fulfilment of their object. Altogether the work is one which cannot fail to become the standard text-book for students of bacteriology, as well as an authoritative work of reference for the practitioner.

ATLAS OF THE DISEASES OF THE SKIN. By H. RADCLIFFE CROCKER, M.D., F.R.C.P., Physician to the Department for Diseases of the Skin, University College Hospital, Formerly Physician to the East London Hospital for Children, Examiner in Medicine at Apothecaries' Hall, London. Edinburgh and London: Young J. Pentland. New York: Macmillan & Co.

FASCICULUS XV. of this series of plates, to which we have on several occasions already referred, opens with a consideration of that so prevalent, so interesting, and still so little understood condition—eczema. Four figures are given in the first plate. Two are of eczema seborrhoicum; neither is remarkably typical; one looking like lupus erythematosus, the other like lupus vulgaris. Eczema verrucosum of the leg is more characteristic, but not just the picture one sees in life as these cases present themselves for treatment.

At first glance one would diagnose pityriasis rubra or dermatitis exfoliativa from the picture to which the name eczema squamosum is affixed. It is probably more instructive to include such a picture than one more commonplace, in order to demonstrate how much care must be exercised in distinguishing these conditions.

Hydroa is the next subject, to which four figures are likewise given, but Fig. 3 might have been omitted, as it is but a slightly enlarged counterpart of the ear of Fig. 2, which shows the sun effects in hydroa aestivale. The next plate is one devoted to lupus vulgaris, showing the several forms, scrofulosus, verrucosus, and papillomatosus, in a clear and instructive manner. The hair and dress in Fig. 1 are painted

in so truly inartistic a manner that it would be preferable to show the parts affected alone, as in Fig. 2.

Lupus erythematosus of the hands and nape of neck is illustrated by some striking and rare examples. One instance is familiar to American readers of the Dermatological Association's Transactions, it having been described by the author upon a recent visit to this country and before the meeting of the Association. Figs. 3 and 4 bear a striking resemblance to lichen planus. Chromidrosis, or seborrhea nigricans, a very rare condition, is indicated by a drawing which shows a deposit of pigmented sebum, or sweat, or both, upon the orbital and cheek regions.

Acne rosacea and rhinophyma form the subject of the last plate, the latter being the better of the two figures. Here again Fig. 3, a side view of Fig. 2, seems superfluous, and the space might have been utilized for illustrating some other condition. The letter-press is instructive, giving valuable hints as to treatment in addition to a clear and concise description of the cases themselves.

THE PRACTICE OF MEDICINE. By WILLIAM C. GOODNO, M.D., Professor of Practice of Medicine in the Hahnemann Medical College of Philadelphia, Physician to the Hahnemann Hospital, etc. With Sections on Diseases of the Nervous System, by CLARENCE BARTLETT, M.D., Lecturer on Nervous and Mental Diseases in the Hahnemann Medical College of Philadelphia, Senior Neurologist to the Hahnemann Hospital, etc. Vol. II. Philadelphia: Hahnemann Press. 1895.

A YEAR ago almost it was that we called attention to the first volume of Dr. Goodno's work, pointing out the rather broad manner in which, for a homœopathic production, the various subjects were treated. In Volume II., which treats of diseases of the circulatory, respiratory, urinary, and digestive systems, diseases of the blood, and constitutional and parasitic diseases, the same conservative manner of writing and the same breadth of thought is noted which caused one to feel, in reading the first volume, that the border line which separates the schools was being grazed. The therapeutical side indicates that true homœopathy is not considered the only guide to the administration of remedies. Much attention is paid to hygienic rules, diet, bathing, and the use of many of the newer drugs, especially in full dose. In reading this work the old-school physician will not find much of that which he is so apt to condemn in homœopathic works, and still the new-school man can scarcely find fault with any of its teachings, since the indication for the remedies recommended is usually set forth with distinctness. The value of modern methods of research, the benefits arising from bacteriological investigations, the worth of laboratory experimentation are all duly appreciated by the writers and have added their influence to the making of a modern exposé of the homœopathic practice of the day. The work seems in every way creditable and commendable.

A TEXT-BOOK OF THE PATHOGENIC BACTERIA, FOR STUDENTS OF MEDICINE AND PHYSICIANS. By JOSEPH MCFARLAND, M.D. Philadelphia: W. B. Saunders. 1896.

DIVIDING his subject into several chapters, the author gives a clear understanding of what a bacteriological workshop is—how to work and what to find.

Part II. deals with specific diseases and their bacteria, and these again are subdivided into, *a*, The Phlogistic Diseases, *b*, The Toxic Diseases. A very good elucidation of how to cultivate any given specific organism, as, for example, that of tuberculosis, leprosy, or glanders, or again the toxic disease germs like those of tetanus, diphtheria, cholera, pneumonia, etc., is carefully given.

OBSTETRIC ACCIDENTS, EMERGENCIES, AND OPERATIONS. By L. CH. BOISLINIÈRE, A.M., M.D., LL.D., late Emeritus Professor, St. Louis Medical College. Philadelphia: W. B. Saunders. 1896.

THIS is a well-arranged work and treats of the usual and unusual physical complications and accidents of the puerperal state. It is essentially a little treatise on emergencies, and can be consulted and studied with great profit by young and old. The accidents of parturition are particularly well presented and will appeal to every physician who is caught with a perplexing case.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, May 15, 1896.

ANDREW H. SMITH, M.D., PRESIDENT, IN THE CHAIR.

Volvulus Ten Days after Operation for Appendicitis.—DR. CHARLES MCBURNEY presented a boy eleven years of age, who had come under his care in the hospital on the last day of February of this year, with symptoms of appendicitis for forty-eight hours. The pain and tenderness had been marked, but the temperature was only 99° F. and the pulse 100. Still, the tenderness extended over a wide area, and the general look of the boy was that of one suffering from a grave illness. The operation was done the same day, and he found extensive lesion of the appendix, which was perforated at two points and partly gangrenous. Two concretions were found lying still in it. Pus and general peritonitis were found in every part of the abdominal cavity except the extreme left hypochondrium. At least, the sponge thrust over to that side did not bring out fluid. The whole cavity was washed out very generously with normal salt solution; it was dried out, and a large glass tube was put down into the pelvis, draining from that point and packing above. Everything went along very satisfactorily, indeed, until ten days after the operation, when the boy began to complain of occasional and scattering pain in the abdomen. This complaint was made with rather increasing frequency for a week, when the symptoms became alarming. There were continuous severe pain, vomiting, and impending collapse. On the surface of the abdomen dilatation of some coils of intestine could plainly be made out, making it sure that there was bowel obstruction from some cause.

Dr. McBurney opened the abdomen a little to the right of the median line, the seat of greatest pain, on March 16th. The intestines were free from adhesions or signs of inflammation, and it was only after considerable search that he found the cause of the obstruction and local distention, consisting of a coil of small intestine held in a position half twisted upon itself by adhesion of the omentum. It was very easy to pull out the intestine, give it half a twist back, and then on closing the wound the boy made a prompt and complete recovery.

The speaker thought that one of the most singular features of these cases of general septic peritonitis with lymph scattered over the entire abdomen, was the fact that when they got well they did not have adhesions, as one might expect, for when occasion arose to open the abdomen again the adhesions were likely to have all disappeared. To have an omental band form of the kind found in this case was unusual.

Appendicitis; Secondary Operation for Extensive Adhesions.—DR. MCBURNEY presented a second patient, a boy, aged six years, who had entered the hospital apparently with an attack of appendicitis of three days' duration, on February 11th. He was a very sick boy, and was operated upon on the day of admission, the incision being made in the usual place. The only peculiar feature found was that the tip of the appendix was the portion which had suppurated, and it lay way over, even to the left of the median line, and was very difficult to find without making a hideously large incision. There was no general peritonitis, simply a localized though rather wide inflammatory process. For two or three days after the operation the boy seemed quite well, except that he occasionally complained of sudden pain. Dr. McBurney watched him with some

anxiety, but after ten days thought it was a temporary affair. On March 10th the boy had continuous pain and began to vomit. There was general tympanites. An incision was made a little farther in than the old one, and most extensive adhesions of the intestines were found. These were finally all separated, and, while he regarded the case as a most hazardous one, the boy from that time had had no trouble.

Tuberculous Leprosy.—DR. F. P. KINNICUTT presented photographs of a case of tuberculous leprosy in a man who had never been outside the United States. He was born in New Orleans, came to New York twenty-five years ago, and had not been more than fifty miles away since. His occupation was that of cook, and he had been employed in various restaurants in the city; nevertheless, his disease had not been recognized until he presented himself at the hospital, supposing he had some throat and rather unpleasant skin trouble. On entering the ward his appearance was so characteristic of leprosy that he was soon turned over to the board of health and was sent to North Brother Island. There was no peripheral neuritis and there were no anæsthetic areas, which Dr. Kinnicutt thought was rather unusual for a case of as long duration as this one would seem to be, judging by the lesions, although the man claimed that the symptoms dated back only a year or eighteen months. There were large ulcers on the tongue, ulcers of the pharynx, of the epiglottis, of the larynx, tuberculous nodules at many points on the upper extremities, particularly the hands and certain parts of the arms, and on the feet. There had been loss of toenails and necrotic spots of the skin covering the toes. He was a lamentable sight.

DR. BIGGS asked where the man had received his infection.

DR. KINNICUTT said that was a most interesting point. He believed authorities were agreed that the usual source of infection was sexual connection with a leper. The colony in Canada, the oldest one in this country (forty or fifty years), was in charge of Sisters of Mercy, none of whom had ever contracted leprosy.

Electrode for Severing Ligatures in Vaginal Hysterectomy.—DR. CLEMENT CLEVELAND showed some small electrodes which he was in the habit of placing in the loop of the ligature on the uterine and other arteries in the operation of vaginal hysterectomy. One electrode was placed on each ligature, and after the lapse of the required number of hours, when there was no longer danger from hemorrhage, the current was passed and the ligature severed. He always ligated the arteries instead of using clamps, and had given up catgut as unreliable, employing Chinese braided silk. It was to meet the objection to silk, that it did not come away soon enough, that he had devised and used the electrodes. The portion of the electrode tied into the ligature loop was fine platinum. Two weeks ago he had removed as many as eight of these electrodes, after severing the ligatures at the end of thirty-six hours, in a single case of vaginal hysterectomy for a fibroid of rather large size. There was less likely to be sloughing of the stump than where the ligatures were allowed to remain. The electrodes were easily sterilized. Their use had never been attended by hemorrhage. An objection to forceps instead of ligatures was that they caused the patient a great deal of distress by their weight.

Chronic Strychnine Poisoning.—DR. CHARLES L. DANA reported a case of chronic strychnine poisoning produced by a proprietary compound containing among other ingredients tincture of *nux vomica*. The patient was a woman who had begun taking the compound about a year before for nervousness following an attack of melancholia. The symptoms which he sup-

posed might be attributed to chronic strychnine poisoning were stiffening of the legs and curling under of the toes while walking, nervousness, and exaggerated reflexes. There were no objective symptoms whatever. There was so great flexion of the toes that at times she walked on the back of them. Dr. Dana had thought that the symptoms might not be dependent upon the medicine, but learned that when this was left off the symptoms disappeared, although she did not feel so well.

DR. PEABODY remarked that some persons were very sensitive to strychnine. Some years ago a doctor had related to him a case of strychnine poisoning from taking homœopathic granules of *nux vomica*.

DR. KINNICUTT remarked that, on the other hand, some patients bore large doses without apparent effects. He had known house physicians in our hospitals to rapidly increase the amount in weak heart of pneumonia, etc., to one-fifth and one-fourth of a grain in twenty-four hours.

DR. C. S. BULL had a patient who was taking half a grain of strychnine a day, but she had begun with doses of one-one-hundredth of a grain.

DR. DANA said that at the meeting of the Association of American Physicians last week he had described a treatment of *tic douloureux*, which included giving hypodermic injections of strychnine, running the dose up within about eight days to one-fifth, sometimes one-fourth, of a grain. There had been no untoward results.

DR. BULL mentioned the case of a man with atrophy of the optic nerve who when he went away from the hospital was to take tablets of strychnine three times a day. He improved so rapidly that he decided on his own responsibility to increase the dosage, expecting to improve that much faster. One afternoon he was led into the infirmary by two men, with every muscle in his body in a quiver, including the muscles of the face, of the extremities, and of the abdomen. It was learned that he had been taking nearly one-third of a grain of strychnine three times a day for nearly a week. It was three to five days before his symptoms subsided.

DR. KINNICUTT said it had been his experience that the physiological symptoms of strychnine subsided quickly, say in twenty-four or forty-eight hours. But he had not seen it given to the extent of producing such marked toxic effects. He asked Dr. Dana what effect one-fifth of a grain had on *tic*.

DR. DANA replied that the treatment had given the best results of any which he had ever employed. Sometimes it had stopped the *tic* for a year and a half, sometimes for only six or ten months, when the course of treatment had to be repeated. In these doses, one-fifth of a grain hypodermically once a day, the strychnine had an anodyne effect, the patient going off into a sort of stupor.

MEDICAL SOCIETY OF DELAWARE.

One Hundred and Seventh Annual Meeting, Held in Newark, Tuesday, June 9, 1896.

THE President, DR. JAMES T. MASSEY, occupied the chair, and there were about fifty members present.

DR. H. G. M. KELLOCK made the address of welcome and called the attention of those present to the many important discoveries of medical interest during the past year. He referred especially to the Roentgen rays, and stated he hoped this would be but the beginning of a practical system which would enable us to view all the organs of the body.

Contagious Diseases of the Lower Animals and Their Relation to the Human Family.—DR. A. T. NEALE read a paper with this title. He referred to the

fact that under the revised code of the Delaware laws the governor has the power to proclaim an epidemic of disease among cattle, to kill live stock, and to take every precaution to protect the lives and property of the public, without doing anything to recompense the individual loser. Continuing, Dr. Neale said, severe as this legislation appears to be, it is in fact almost inoperative, for the live-stock owner, recognizing that the majority will pay no heed to the individual loser and that quarantine will add materially to his loss, quietly removes his dead from sight, and before he or his neighbors are awake to the fact, sometimes has a fully-established epidemic upon his own and upon the adjoining farms. There should be amendment of the present laws, giving permission to the governor to employ State funds in the purchase and use of protective vaccines, whether they be those of anthrax, of rabies, or of any similar disease—permission to use funds in the interests of the individual, just as he is now empowered to use them in the employment of the sheriff.

DR. BLACK said he entirely agreed with Dr. Neale as to what should be done in this matter. In his opinion about twenty per cent. of milk cows are tuberculous, and he believed that many of the summer complaints of children were due to this cause. He advocated the sterilization of milk and stated it should always be brought to the boiling-point a second time.

Discussion on Malaria.—DR. JAMES H. WILSON read a paper on "The Source and Cause of the Irregular Form of Malaria." He thought that the term malaria is synonymous with swamp or ague poison, and that the intermittent and remittent forms of the disease are due to the same cause, the difference in type being generally supposed to be only a difference in degree. Thayer and Hueston, in the course of their studies, reached the conclusion that the tertian type of fever depends on the presence in the blood of a parasite that passes through its cycle of existence in about forty-eight hours, and the segmentation of this organism at intervals of about forty-eight hours is always associated with a febrile paroxysm. In regard to the æstivo-autumnal fever, the same authors conclude that it is due to the organism described by Marchiafava and Celli, but that the cycle of existence of this parasite has not yet been followed out in an entirely satisfactory manner. The main seats of infection are the spleen, bone marrow, and internal organs. In the opinion of Dr. Wilson the mode of infection of irregular forms of malaria is doubtless identical with that of the regular forms; that is to say, the method of admission into the system is similar.

The typho-malaria referred to by Dr. Woodward during the late rebellion was typhoid fever with malarial complications and the clinical thermometer has placed this affection where it properly belongs.

DR. JUDSON DALAND stated that while it was doubtless true that many cases of malaria were acquired through the drinking-water, yet unquestionably many cases were acquired through the atmosphere. Out of sixty or seventy cases studied by the speaker, eighty per cent. were of the tertian variety and, therefore, the few irregular cases could be easily explained. The remittent form is unquestionably due to the same cause as the intermittent.

In the opinion of the speaker many cases of malaria were instances of double infection; that is to say, at the time the malarial intoxication was acquired another parasite, the *amœba coli*, was also taken.

DR. WILLIAM C. PIERCE, of Wilmington, read another paper on malaria. He spoke of the geographical distribution of malaria in the United States and Europe. He referred to the effects of the soil in producing malaria and stated that several species of the plasmodium may coexist and produce the most varying types of the disease. He then referred at some

length to two cases of malaria which recurred many years after they were supposed to have been cured, and one case was especially interesting from the fact that it recurred five days after the termination of labor, the woman having had no symptoms of malaria for some years previous.

DR. C. M. ELLIS referred to one fact which in his opinion has been almost entirely overlooked by the profession, and that is that the malarial poison passes through cycles the same as many other diseases. He gave a practical demonstration of this by mentioning localities and periods of time of the recurrence of malaria. He stated he had never seen a case of true remittent malaria as described in the books during fifteen years of practice.

DR. JUDSON DALAND, in discussing this paper, referred to the comparatively few cases seen in Pennsylvania as compared with the number seen in Maryland and the surrounding country. Concerning the question of malarial cycles, Dr. Alfred Stille, of Philadelphia, used to say that a similar condition existed along the banks of the Schuylkill River years ago.

DR. JOHN B. BUTLER, of Newark, asked how one would make a diagnosis between continued fever and typhoid fever.

DR. VALLANDIGHAM gave the details of an interesting case of malaria which had come under his notice some time since and which continued to recur immediately the administration of quinine was stopped. The patient was a man about fifty years of age, a paper hanger, and presented the appearance of a case of typhoid. The malaria was finally cured by the continued administration of large doses of quinine.

DR. R. G. ELLEGOOD stated that many years ago remittent fever was quite prevalent and he had seen as many as eight or ten persons suffering from this affection at the same time out of a family of fifteen. None of these cases would present any typhoid symptoms whatever, but would be typical cases of remittent malaria.

DR. R. B. HOPKINS read a paper on the "Treatment of Malaria."

The author mentioned various remedies which he found efficacious in the treatment of different forms of malaria, and stated that in his opinion the reasons that this disease is not so prevalent as it used to be are to be found in atmospheric changes, improved condition of the soil, better drainage, and better water supply.

Referring to the diagnosis of malaria, DR. DALAND stated that the one pathognomonic sign of this disease was the presence of the malarial parasite. In forty-eight hours this parasite completely changes its appearance, during which time it will enter a red blood cell, feed upon the contents of the cell, and increase in size at the expense of the stroma of the red blood cell. Nothing resembles this appearance in health or disease, and the diagnosis of malaria is complete as soon as this parasite is discovered.

The speaker then passed around a number of photographs illustrating the process described and referred to the theory which has been advanced that the rupture and disintegration of the mature malarial body is coincident with the occurrence of the chill.

Pernicious Anæmia.—DR. MARSHALL reported a case of pernicious anæmia in which the diagnosis was difficult to determine between leukæmia, Addison's disease, and pernicious anæmia. The patient was a bank teller, thirty-three years of age, who had a pulse of 12 and a temperature of 102° F. when Dr. Marshall was called to see him. The blood count at this time showed 1 white to 235 red, the red then numbering about 1,300,000. The diagnosis of pernicious anæmia being thus confirmed, the patient was placed upon red bone marrow and arsenic and in a few weeks the red blood corpuscles numbered 2,500,000. Two weeks

later the count showed 3,500,000 and in another two weeks 3,800,000. Three months thereafter the count showed 4,400,000. The patient continued to improve and was able to return to his duties.

Obstetrical Complications.—DR. C. M. ELLIS read a paper with this title.

The author especially emphasized the great danger of the convulsions of pregnancy before term and the urgent necessity for artificial delivery when they occur. His own experience included eight cases occurring in the seventh, eighth, and ninth months of pregnancy, and showed clearly that when a convulsion occurs before term, unless it is of systemic origin, the rule for immediate delivery should be imperative, and without regard to the presence or absence of uterine contractions or the condition of the os as to dilatation. The earlier the convulsion begins, the greater the need of emptying the uterus by the most expeditious methods, all palliative medicinal treatment being secondary to this one great object. This procedure is necessary because of the great fatality of eclampsia before term, which is fully fifty per cent. of all cases. This high death rate is greatly exceeded when the delivery is not accomplished or if it is delayed until several convulsions have occurred or until uterine contraction and dilatations have supervened.

Dr. Ellis stated that he had never seen a death occur before delivery after the operation had been initiated and in his opinion there should be no delay in evacuating the uterus after the first convulsion. The earlier albumin appears in the urine the more imminent is the danger of eclampsia, and if this accident threatens it may be incumbent on the attendant to hasten delivery without waiting for the actual convulsive seizure. In concluding his remarks the speaker denounced the indiscriminate use of morphine hypodermically in these cases.

Dr. Ellis stated that in bleeding his patients he always took into consideration as of primary importance the patient's physical condition.

DR. GEORGE M. BOYD, of Philadelphia, entirely agreed with Dr. Ellis and advised in addition, as medicinal treatment, chloral by the rectum. In his opinion the mortality depends to a great degree on the extent of the kidney lesion, as in many cases of interstitial nephritis existing before pregnancy eclampsia develops during labor.

DR. P. W. TOMLINSON, of Wilmington, mentioned a case in point, in which twenty-four ounces of blood were drawn and decided improvement followed. The patient was delivered of an eight months' child twenty-four hours after the operation and entirely recovered.

Cardiac Diseases as Encountered in Central Delaware.—DR. E. S. DWIGHT read the paper. He referred to the curious circumstance that frequently commencing heart lesions were evidently due to the absorption of some morbid product through the abraded surface of the bladder. He believed that ulcerative endocarditis had been the cause of death in one of his cases of eclampsia, in which the patient's debility would not permit of bleeding. When ulcerative endocarditis can be recognized before embolisms have occurred, it is of paramount importance that the patient should be kept in a recumbent position and all movements avoided as much as possible.

A Pin in the Appendix.—DR. H. J. STUBBS, of Wilmington, read a paper entitled "Three Cases of Appendicitis, One of Unusual and Fatal Complication." He related the details of the three cases and the remarkable fact about one was the presence of a pin within the appendix. He strongly urged the importance of early diagnosis and prompt medical and surgical treatment of all cases of appendicitis.

Officers.—DR. WILLIAM P. ORR, of Lewes, Del., was elected *President*; Dr. Willard Springer, of Wilming-

ton, *Vice-President*; Dr. P. W. Tomlinson, of Wilmington, *Secretary*, and Dr. William C. Pierce, of Wilmington, *Treasurer* for the ensuing year.

The society adjourned to meet in Rehoboth in June, 1897.

Clinical Department.

A CASE OF HERMAPHRODISM (?).

By CARL BECK, M.D.,

PROFESSOR OF SURGERY, NEW YORK SCHOOL OF CLINICAL MEDICINE; VISITING SURGEON TO ST. MARK'S HOSPITAL, GERMAN POLIKLINIK, WEST SIDE GERMAN DISPENSARY; CONSULTING SURGEON H. S. G. S. ORPHAN ASYLUM, ETC.

TRUE hermaphroditism (*Ἑρμῆς* = Hermes = Mercury, and *Ἀφροδίτη* = Aphrodite = Venus), that is, the presence of both sexes in one individual, is still doubted, though many apparent cases are reported. Undoubtedly there are varying degrees of hypospadias, while rudimentary analogous organs of the other sex coexist.

In view of the similarity of the male and female sexual organs during the first two months of embryonic life, it is readily comprehensible how a slight intra-uterine disturbance may prevent union of the halves of the uro-genital sinus, or how further development of the tubular prolongation anteriorly may be interfered with by the change of the external organs.

In some cases the sex can be differentiated only with difficulty. A hypospadiac showing cleft scrotum, a miniature penis, and retained testicles, resembles a female so much that it may be baptized as a female, and years later, to the great terror of the parents, its male character manifests itself by the descensus testiculorum as well as by the development of masculine inclinations.

Two weeks ago, through the kindness of Drs. Ferd. C. Valentine and William S. Gottheil, a case of this type was referred to me.

L. M——, twenty-one years of age, born in the State of New York, admitted to the surgical department of St. Mark's Hospital, June 9th, 1896, gave the following history: He was baptized as a girl, but a few years later he was again baptized as a boy.

He had children's diseases, but never suffered from

right side swelled to considerable size. They were extirpated in a hospital of this city, where antispecific treatment was also given. A few weeks ago he lost his appetite, had chills, and gradually became weaker. At the same time he noticed a hard mass below his umbilicus, which at first was not painful, but troubled him later.

When I first saw him this very poorly nourished individual had a pulse of 124 and a temperature of 101.8° F. He was apparently a man, had a beardless face, and a feminine voice and form. Height, five feet eight inches. Weight, eighty-six pounds. Mammæ slightly enlarged. The penis, two and one-third inches long, was perfect so far as the glans and corpora cavernosa were concerned, but the urethra was represented by a mere depression. In the centre of this groove two prominences, consisting of skin tissue, were present,

FIG. 2.

one about one inch distant from the glandular end of the penis and the other one an inch farther downward.

They indicated where the penis was formerly attached to the infundibulum below, whence it was dissected one year ago (Figs. 1 and 2).

Instead of the scrotum there were two well-developed labia majora of equal size. They contained no testes and were not sensitive to the touch.

Beneath the arch of the pubis was a red-lined infundibulum, which resembled an introitus vaginae most markedly and which showed four orifices.

The largest orifice was at the lower end of the infundibulum and permitted only of the introduction of a metal sound (22 F.). On pressing my little finger against this meatus, a thin semilunar membrane (rudimentary hymen [?]) yielded. Now I could introduce my middle finger easily into a canal, four inches in length (undoubtedly the vagina), at the end of which a well developed uterus could be felt. The rupture of the membrane was followed by a slight hemorrhage.

On the upper edge of the infundibulum the orifice of the urethra was plainly visible. On each margin of the infundibulum, about one-half inch above its lower end, was a small orifice, admitting only a very thin probe for a distance of one-third inch. The patient claimed that ejaculation of sperma took place through these orifices. He maintained that since he was fifteen years old he had connection with women at least three times a week. He also claimed that he had erections, his penis enlarging to double size then. Only three or four drops, as he stated, were ejaculated at a time. There was never any trace of menstruation.

The inguinal glands were slightly enlarged. The abdomen showed nothing abnormal, except a slight bulging above the symphysis. Upon palpation a

FIG. 1.

any serious sickness until eighteen months ago, when he acquired an ulcer on his rudimentary penis, which he termed a hard chancre, and which healed under the use of an antiseptic. He also claimed that several weeks thereafter an eruption over the whole body followed. One year ago the submaxillary glands on his

mass, filling up the space between the right iliac fossa and the umbilicus, was detected. This mass could not be displaced, was painful on touch, and of an irregular, nodular shape. At some points slight fluctuation could be elicited. Aspiration of the tumor yielded blood. Harpooning of the tumor tissue revealed round cells under the microscope.

On June 13th I performed laparotomy at St. Mark's Hospital. After the incision in the linea alba was made, about one pint of a thin, serous, colorless fluid escaped from the abdominal cavity. The tumor was found tightly adherent to the peritoneum. On two portions the peritoneal tissue had disappeared entirely,

FIG. 3.

and instead of it a mass of the same structure as that of the tumor, being of the size of a dove's egg, was noticed on either portion. They were extirpated. After the many adhesions to the intestine and to the parietal peritoneum were separated the tumor could be drawn outside of the abdominal cavity, and was recognized as the right testicle, hanging to a thick pedicle, which was found to be the cord. This, however, resembled a tube much more closely in shape, and was attached to the parietal peritoneum about one and one-half inches laterally from the symphysis and about one-half inch below the upper margin of the os pubis.

After the pedicle was tied and the tumor dissected from it, another tumor of the same consistence and of much smaller size was detected on the left side far down in the pelvis. It was of the same renal-like shape as its fellow, and was attached to the peritoneum in the same manner, the pedicle being much smaller. Its removal was undertaken in the same manner. No adhesions were found (Figs. 3 and 4).

FIG. 4.

Further inspection of the abdominal organs revealed nothing abnormal, except the presence of a considerable number of small, hard nodules, ranging from the size of a head of a pin to that of a pea, in the serosa of that portion of the small intestine which had been adherent to the right testicle.

There was considerable shock at the end of the operation, which fortunately could be done rapidly, but by severing the adhesions considerable loss of blood occurred. Nevertheless, the patient made a good recovery.

The larger one of the tumors weighs three pounds, the smaller one eight ounces. The fibrous structure of the larger tumor is interspersed with small cysts, which contain a light yellowish fluid of a gelatinous consistence. Microscopical examination showed it to be a soft, round-celled sarcoma.

As soon as the patient's condition permits I shall perform a plastic operation for the formation of a penile urethra, according to Thiersch's method.

The patient was examined by Drs. H. J. Garrigues, L. B. Bangs, J. G. Wallach, Irwin, Sprague, Dowling, Johnston, Little, Schoeneberger, Cavanagh, and others.

TWO CASES OF DELIVERY AT FULL TERM FOLLOWING CUL-DE-SAC OPERATIONS.

BY BENJAMIN TORRENS, M.D.,

NEW YORK.

IN view of the important field opened up by the cul-de-sac as an avenue for operative procedures in the treatment of pelvic lesions, a report of the following cases may be of interest, for they are, as far as I can ascertain, the first two cases of pregnancy following cul-de-sac operations for the treatment of adherent retroposed uteri reported in this country.

These two patients, whom I attended during their pregnancy and confinement, were operated on by Dr. W. R. Pryor for adherent retroverted uteri by a new method, described by him in the *MEDICAL RECORD*, July 20, 1895. Their histories are briefly as follows:

CASE I.—Mrs. K—, aged twenty-two, married three years. Pelvic and general condition at the time of marriage was normal. One month later she became pregnant. At the eighth month she was delivered of a fourteen-pound child. The woman was attended by a midwife. Labor was difficult, lasting twenty hours; the perineum was lacerated; the child was still-born. Infection evidently occurred, as the woman had an attack of pelvic peritonitis, accompanied by fever, pelvic pain, and severe hemorrhages, which continued for a month, followed by profuse leucorrhœa, abdominal pain, and backache.

Eight months later she again became pregnant, carried the child three months, and miscarried. She had another attack of pelvic peritonitis, and up to the time of operation, two months later, suffered from continuous flooding and constant pelvic pain.

The cul-de-sac was opened and the adhesions between the uterus and pelvic floor were broken up. Both tubes being occluded, their simbrated extremities were dilated, the ovaries and tubes were set free from their adhesions and replaced, the uterus was curetted and replaced; after which there was a cessation of all the previous symptoms. The uterus remained in perfect position, and pregnancy took place four months later. For the first six weeks of pregnancy there was some slight gastric disturbance, after which time it ceased. Throughout the remainder of her pregnancy the digestive functions were normal, and there was at no time the slightest attempt at abortion. The woman came to full term and had a perfectly normal labor.

On May 21, 1896, at 8 P.M., true labor pains began. On examination the cervix was small and soft. The internal os admitted two fingers. Position of child, vertex L. O. A. Uterine contractions were regular and of good force. Duration of first stage, two hours and forty minutes.

At 10:40 P.M. the cervix was fully dilated; the membranes were ruptured, the patient had several strong pains, the head descended rapidly and presented at the vulva. Flexion of the head was maintained by pressure through the rectum against the nasal eminence of the frontal bone, and the head was

delivered during an interval between the pains. The shoulders were rotated and delivered in the same way. Duration of second stage, twenty minutes.

The third stage lasted fifteen minutes. The placenta and membranes came away intact. The uterus contracted firmly and hemorrhage was very slight. Duration of labor, three hours and fifteen minutes.

The puerperium was normal, the uterus remained firmly contracted, there were no after pains, the lochia ceased on the sixth day. The only complication was a slightly caked breast, which was easily overcome by hot stupes and massage. Lactation was normal and the woman nursed her child. A rapid and perfect involution took place, and the uterus when last examined was in normal position.

CASE II.—Mrs. G—, aged twenty-seven, married six years. Became pregnant one month after marriage, went to full term, and was delivered of a healthy child. After labor she had an attack of pelvic peritonitis, accompanied by fever, flooding, pelvic pain, and tympanites. Two years later she was again pregnant and aborted at the seventh month. One year later she became pregnant and again aborted at the seventh month.

On April 21, 1895, the patient was operated on. In addition to the same pelvic conditions as were found in the previous case, namely, adherent retroverted uterus and occlusion of both tubes, there was also found a large cyst of the left ovary, which was punctured, and the same method of treatment was adopted for the other conditions. The operation was followed by a complete relief of pelvic symptoms. The uterus remained in perfect position and pregnancy occurred about September 15, 1895, five months after the operation. During pregnancy there was absolutely no gastric disturbance nor any attempt at abortion: the woman, in fact, going somewhat beyond full term.

Labor pains began July 1, 1896, at 4 P.M. On examination, the cervix, which had been large and hypertrophied, was found somewhat softened; the internal os admitted one finger. Position of the vertex, R. O. A. The pains were of good force and regular, but dilatation of cervix was slow, on account of its hypertrophied condition. Duration of first stage, twelve hours.

After complete dilatation of the cervix was established, the membranes were ruptured artificially, and the second stage was completed in thirty minutes.

After waiting the customary fifteen minutes to allow the uterus to contract, the placenta was expelled by Credé's method. Duration of labor, twelve hours and forty-five minutes.

The puerperium was normal and uncomplicated. The uterus remained well contracted. The lochia ceased on the seventh day. Involution is progressing rapidly, but it is as yet too early to speak of the ultimate position of the uterus after involution is complete.

The special point of interest in the above cases was the entire absence of any attempt at abortion in uteri which had previously miscarried twice consecutively. Though there was a perineal laceration in each case, no plastic work had been done. In neither case did the scar in the cul-de-sac give rise to any trouble, the scar tissue having so completely disappeared as to be undetected.

435 PLEASANT AVENUE.

Thyroid in Lupus.—Malcolm Morris cites (*British Journal of Dermatology*) a case of lupus of long standing with extensive destruction of nose, cheeks, and neck. By the use of thyroid, one to five tabloids daily, the ulcers healed and the disease progressed satisfactorily.

TREATMENT OF LARYNGEAL CROUP.

By A. LLEWELLYN HALL, M.D.,

FAIR HAVEN, N. Y.

In my experience I have found no remedy so thoroughly effectual for the relief of simple laryngeal croup as quininæ sulphas. As a prophylactic for laryngeal spasm it has no therapeutic rival and in this respect it is a blessing to every croup-afflicted household. I have repeatedly tested the efficacy of the agent during the past fifteen years without noting a single failure. I am aware that such sweeping statements tend to incite disbelief rather than to inspire faith; but if the drug be given with due regard to appropriate dosage and timely administration the success attending its use will, I believe, amply demonstrate its value.

The following method of administration gives excellent results: For a child from two to five years of age the dose is from one-half to one grain given at intervals of two to four hours. Usually the first three or four doses should be administered at the shorter interval mentioned and then uninterruptedly continued at the longer interval for two or three days, or until the disease is at an end. Frequently the first two or three doses are rejected on account of the bitterness of the remedy, but tolerance is quickly established and a croupy child under gentle discipline readily learns to take quinine without special repugnance.

CHILDBIRTH WITH UNRUPTURED MEMBRANES.

By J. W. KALES, M.D.,

FRANKLINVILLE, N. Y.

If unruptured membranes at birth are of such rare occurrence as the medical journals say they are, perhaps the following is worthy of record.

Twelve years ago I was called to see Miss W—, a strong, robust girl aged about sixteen. She was in active labor and had been for some hours. Full nine months had elapsed since the date of conception.

Vaginal examination showed that the whole vagina was filled with protruding membranes, which appeared stronger and thicker than usual. As labor seemed to progress favorably and no indications for interference with nature's process were apparent, I concluded to await results. The natural labor pains continued about one-half hour, when the fœtus, completely enveloped in the unruptured membranes, was expelled. Absolutely no assistance had been rendered. The labor at full term was in all respects normal. I carefully examined the membranes while intact. They presented an ovoid about twelve inches long and eight inches in diameter. The child could be plainly seen through the translucent membranes. It was in a state of complete repose, chin flexed upon the chest, arms crossed upon the chest, legs flexed upon the thighs, and thighs flexed upon the abdomen. Not the slightest motion or sign of life was visible through the membranes in the dim lamplight. The child seemed to be of the same specific gravity as the amniotic fluid, for it floated in the centre of the fluid and was retained by the funis, which resembled a slack cable attached to a buoy. Several blood-vessels were seen ramifying over the membranes. The least touch caused the mass to fluctuate like a closed bladder nearly filled with water. Having completed the examination, I ruptured the membranes. As soon as the air struck the child it gasped once or twice and then screamed. Further examination revealed a healthy male child weighing about eight pounds. I have in my possession a specimen of a fœtus enveloped in its membranes which was expelled without external agency during the third month. These are not uncommon.

Therapeutic Hints.

Method of von Troeltsch.—Take a portion—say a tablespoonful—of the gargle in the mouth, hold it in the back of the throat with the head thrown back; then, closing the nose with the finger and thumb to prevent entrance of air, open the mouth and make the movements of swallowing without letting the liquid go down the throat.

Summer Diarrhœa of Children.—Astringents which were formerly so extensively used have very properly been relegated to the waste dump as useless. 1. Summer diarrhœa is caused largely by improper and unclean feeding, and is usually preventable. 2. Bacteria play a very important part in its development. 3. Hot weather has to do only in an indirect manner, as it promotes the growth and development of bacteria in the food supply. 4. Treatment consists, first, in eliminating all decomposing food from the bowels by cathartics, lavage, and colonic irrigation. 5. Drugs judiciously administered are of great value, but are secondary in importance to prevention and management.—DR. KARDIN (*Cincinnati Lancet-Clinic*).

Excoriations in Children.—Dr. Pritchard prescribes the following:

R Acid. salicyl.....	gr. viij.
Bismuth. subnit.....	ij.
Amyli.....	iss.
Ung. aq. rose.....	℥i.

Treatment of Phagedenic Soft Chancres.—Bathe the affected parts for ten minutes several times daily with water at a temperature of 105° F. The pus loses its virulence at that temperature. The phagedæna subsides and the general health improves.—*Therapeutic Gazette*, December, 1895.

Gall Stones.—

R Ol. terebinthinæ.....	℥v.
Syrupi acaciæ.....	℥ss.
Sodii sulpho-carbolat.....	gr. xx.
Spirit. ætheris comp.....	℥xv.
Aquæ menthæ piperitæ.....	q.s. ℥i.

M. S. To be taken twice or thrice daily.

Hot poultices should also be applied to the hepatic area.—*Therapeutic Gazette*, January 16, 1896.

New Treatment for Tapeworm.—Dr. Newington (*Medical Times and Hospital Gazette*, December 21, 1895) gave the following for another disorder and found that the patient passed a dead tapeworm eleven feet long, of whose presence he, as well as the physician, was ignorant:

R Potass. hydriodidat.....	gr. xxxvi.
Iodi.....	gr. xij.
Aquæ.....	℥i.

Ten drops in water three times daily.

The same combination was then tried in three cases in which the parasite was known to be present and in each case it acted equally well. In still another case, which had resisted all previous attempts, the patient passed a mass of dead tapeworm and for a year had no return.

Ergot.—Dr. Franklin H. Martin (*Journal of the American Medical Association*, March 21, 1896) says the physiological action of ergot is accounted for by its effect upon unstripped muscular fibre. It contracts blood-vessels and hence increases blood tension. It acts upon the uterus in four ways: 1. It decreases the bulk of the organ by producing a steady tonic contraction of all its muscular fibres. 2. It decreases the whole bulk of the organ by decreasing the amount of blood in its walls. 3. By decreasing the amount of

blood in the uterus it modifies materially its nutrition and decreases the amount of the menstrual flow of blood. 4. Given in large doses it produces tonic contractions of the muscular fibres, and by instituting clonic contraction of its fibres causes expulsion of bodies from its walls and cavity.

Iodoformed Vaseline in Bubo.—Rullier (*Arch. Med. Mil.*) writes that the idea of treating buboes in this manner was inspired by the recommendation of Laub to incise the swelling and inject nitrate of silver. He employs a ten-per-cent. solution of iodoform in vaseline melted by heat, which he injects after making a small opening and evacuating the pus. Failure happens only when the skin is lacking in sufficient vitality.

Thyroid Gland in Severe Syphilis.—The patient, twenty-five years of age, had lost the alæ nasi and the upper portion of one ear by ulceration, and the general condition was very bad. The beginning dose was two grams, increased to fourteen after a time, of the fresh gland chopped up and eaten with bread, butter, and salt. Every second day the treatment was interrupted for twenty-four hours. After five days there was marked improvement and a cure in five months.—GOULADSE (*Méd. Mod.*, October 5, 1895.)

Psoriasis.—Iodide of potassium in gradually increasing and large doses, or oleoresin copaiba, five minims three times a day.

Digitalis Poultices for suppression of urine.

Endocarditis.—As soon as the heart sounds in acute articular rheumatism begin to grow muffled or a bruit is detected, give, in addition to the salicylate, iodide of potassium, 0.60 centigrams three times daily. Also flying blisters over the apex and along the course of the fourth, fifth, and sixth intercostal nerves.—*Canton Clin. Med.*

Constipation.—Many affected with constipation do not drink enough water, whether hot or cold. There is not enough fluid in the body for the normal secretions and eliminative fluids, a condition which should be remedied.—CUTTER.

Polymyositis Acuta.—Dr. Herrick (*American Journal Med. Sciences*) concludes as follows: 1. There is a definite disease primarily affecting many muscles of the human body and described as polymyositis acuta, pseudo-trichinosis, or dermato-myositis. 2. Inflammatory swelling of muscles, exanthema, splenic tumor, extension to the muscles of deglutition and of respiration, death, characterize the most typical cases. 3. Atypical and milder cases indicate that either the disease may run a benign course or that in the absence of definite means of differential diagnosis forms etiologically differing are confused. 4. Trichinosis and polyneuritis must always be excluded. 5. Syphilis may attack many muscles and, resembling acute polymyositis, must be excluded. 6. The etiology is still unknown. 7. Three hypotheses can be advanced as to its cause: (a) That it is due to a specific micro-organism (vegetable parasite). (b) That it is due to a chemical poison (toxin). (c) That it is due to an animal parasite (gregarina). 8. In doubtful cases the excised piece of muscle should be examined not alone for trichinæ and bacteria, but, as well, by special methods for protozoa. 9. Failure to find trichinæ in all areas showing inflammatory reaction, or even in the majority of such areas, does not exclude trichinosis as the primary cause of the myositis. Only repeated failure to find trichinæ after thorough examination enables one positively to assert that the case is not one of trichinosis. (Compare examination of spu-

tum or tissue for tubercle bacilli.) 10. Syphilitic myositis occurs in three forms—the gummous, the diffuse, the combined. 11. The diffuse syphilitic myositis is usually a late manifestation of syphilis; appears without definite exciting cause; affects no particular muscle by preference; often involves more than one muscle; may resemble acute polymyositis.

Gastralgia.—

Seasickness.—Dr. M. Charteris (*Practitioner*) thinks that as a rule passengers commence their voyages under conditions unfavorable to exemption from seasickness. They eat heartily, and when the steamer gets under way their stomachs rebel. The irritated gastric state is communicated to the vomiting-centre in the cerebellum, and when vomiting has ceased retching begins. In a long voyage the diet for the first two days should be spare and dry. A full meal should not be eaten. Soups and pastries should be avoided. The same injunction applies to short voyages. Diet, though a very important prophylactic, will not guarantee exemption from seasickness. The following means have been found successful: (1) A clearing out of the primæ viæ, not by saline, but by a liver-acting aperient, as calomel or blue pill, taken on the night before embarkation. It should be followed in the morning by a saline purgative, as citrate of magnesium. (2) When on board the steamer, if the passage be by night, a full dose of the solution of chloral-amide and bromide of potassium (chlorobrom) should be taken and the passenger should retire. If the passage be by day a minimum dose should be taken and the passenger should remain on deck. Only in rare instances is a second dose necessary.

Supraorbital neuralgia and asthenopia are frequently due to nasal irritation.

Chilblains.—In the intense form of chilblains without ulceration the parts should be enveloped in aseptic compresses wet with a decoction of walnut leaves, using from one and a half drachms to one-half an ounce of leaves to one quart of water. The whole should be covered with an impermeable dressing. After the irritation has somewhat subsided apply the ointment or powder:

R Boric acid..... gr. xv.
Tannic acid..... gr. v.
Vaseline..... 3 iiss.
M.
R Starch,
Lycopodium..... āā 3 iiss.
Tannic acid..... gr. v.

The decoction of walnut leaves may be applied morning and night and during the day the ointment or powder may be used, gloves being worn. When ulceration exists the wound should be washed with a solution of mercuric chloride, 1 to 1,000, and the compresses wet with a solution of 1 to 2,000. The ulcerated part may be touched with tincture of iodine or camphorated naphthol, and then covered with aseptic gauze impregnated with borated vaseline or glycerole of starch. If granulations have formed, the stick of silver nitrate may be applied. If these measures fail, ointment of zinc oxide may be used. Cod-liver oil or iron iodide may be administered if required. As a prophylactic those susceptible to chilblains should keep active when exposed to cold and should avoid long exposure and violent changes of temperature. A pill constituted as follows may be taken internally from two to four times daily:

R Quinine sulphate,
Ergot..... āā gr. 3/4
Powdered digitalis leaves..... gr. 1/2
Extract of belladonna..... gr. 1/8

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE WELSH UNIVERSITY—PRINCE OF WALES INSTALLED AS CHANCELLOR—MIDDLESEX HOSPITAL CONVALESCENT HOME—THE "QUEEN'S NURSES" RECEPTION AT WINDSOR—LADY DUFFERIN'S MEDICAL FUND—PRIZES AT THE UNIVERSITY COLLEGE—CIVIL RIGHTS AND THE MEDICAL COUNCIL—THE BOWMAN LECTURE—PROFESSOR CURNOW—THE LATE DR. CHOLMELEY.

LONDON, July 3, 1896.

THIS day a week the Prince and Princess of Wales went to Aberystwyth, where they were received with the utmost enthusiasm by all classes of society. Mr. and Mrs. Gladstone also went and their reception was almost if not quite as enthusiastic. The event which drew them to the principality was the installation of the Prince as chancellor of the University of Wales, an institution which promises to be of great value to science as well as other academic faculties. The inauguration was celebrated with all the pomp and circumstance of the new seat of learning. As soon as the Prince was installed and received the degree of D.C.L., he proceeded to confer the honorary degrees, the first recipient being the Princess, who was duly made a doctor of music amidst what is described as the wildest enthusiasm. The next recipient was Mr. Gladstone, who was made LL.D., as also were Lords Spenser and Herschell, the chancellors of the universities of Victoria and London. After the ceremony a visit to the college was made and after that there was a luncheon. Three toasts only were given—the Queen, the Prince and Princess, and the university and its colleges. The chancellor was proposed by Mr. Gladstone in one of those felicitous speeches in which the aged statesman so much excels. And the reply of the Prince was equally happy in thanking the proposer for coming to Aberystwyth at his advanced age, and giving him the flattering opportunity of conferring an academic distinction upon one who had attained the highest position of a statesman as well as a great reputation in literature and scholarship.

On Wednesday their Royal Highnesses the Duke and Duchess of York opened a grand fête in aid of the new convalescent home which has been established in connection with the Middlesex Hospital at Clacton-on-Sea. The Middlesex is one of the oldest of the London hospitals, and, though now situated in a densely crowded part of the metropolis, was built in Marylebone Fields nearly one hundred and fifty years ago.

Yesterday was a grand day for the "Queen's nurses." About four hundred went to Windsor and were received at the castle by Her Majesty. The "Queen's nurses" have all been trained and are in connection with the Jubilee Institute which was founded by the Queen and endowed with some £70,000, the amount raised as the "women's offering" on the completion of the fiftieth year of Her Majesty's reign. Besides an array of royalties in attendance, the council of the institute was present, including Sir James Paget, who is a trustee of the fund. The nurses were drawn up in a square open on one side and received their sovereign with a low courtesy in unison. The Queen then addressed them, saying: "I am very much pleased to see my nurses here to-day and to hear of the good work that they are doing, and I am sure they will continue to do it." The nurses then sang a verse of the national anthem and filed before the royal carriage in pairs. Luncheon was provided

on arrival and tea later in the afternoon. The nurses visited St. George's Chapel and the State apartments, and returned to town to be further entertained in the evening by the Duke of Westminster.

Another event yesterday was the opening of a garden fête by the Marchioness of Dufferin on behalf of the fund associated with her name for supplying medical aid to the women of India. The treasurer said that during the ten years that have passed since Lady Dufferin began the work £400,000 has been given by native princes, seventy hospitals have been established, and three millions of women medically treated. In a grateful little speech Lady Dufferin said the fund dealt with a whole system of hospitals, dispensaries, medical education, and nurse training, and was destined to bring medical aid within the reach of all women in the Indian Empire. It has already enlisted the support of all the creeds and all the races in that vast empire.

Yet another function of yesterday may be named. Sir J. Erichsen distributed the prizes in the faculties of arts, science, and law at University College. Sir John urged the claims of culture and science on this somewhat "huckstering" age.

The Civil Rights Defence Committee is making a good fight respecting the case of Dr. Anderson. They appealed to the Medical Council to receive a deputation, but the executive committee did not offer facilities. The president, Sir R. Quain, has, therefore, been addressed by the chairman, Mr. Timothy Holmes, in a letter which sets out the case with great clearness and shows why the council should take some part in defending the rights of a registered practitioner. The Apothecaries' Society has also been approached, and it is hoped will assist in defending one of its licentiates and perhaps obtain the co-operation of other city guilds in the protection of chartered rights.

The Bowman lecture established by the Ophthalmological Society in memory of the late Sir William Bowman was this year delivered by Professor Snelling, of Utrecht. After an eloquent tribute to Bowman's memory and a reference to the demands made by the state on the ophthalmic surgeons of the present day, the learned professor described the results of some of his own investigations on vision and retinal perception. He pointed out that the act of vision is not confined to the perception of stationary retinal images, as the movements of the eye bring every part of the image over the centre of the fovea. He had investigated the dependence of acuteness of vision on the amount of illumination. When this reaches a certain degree of intensity the unprotected eye is not conscious of a further increase of luminosity. The acuteness of binocular vision is higher than monocular with every degree of illumination, but not to the extent some have stated, as equalling double the light. In the new hospital at Utrecht special arrangements have been made for lighting the operating-room. As visual power is heightened by adaptation of the eye for a weaker light than that on the observed object, the walls, ceiling, and floor have been painted black, light being admitted only through a window directly on the patient, so that the operator may employ the maximum of his vision. This plan excludes also troublesome reflexions from the cornea and the patient's gaze can be fixed in any direction by the flame of a candle, which can be well seen against the dark walls. The adaptation of the eye to light was the next point. The sensibility of the retina changes under the influences of light and darkness, the time required for this corresponding with that of the formation and disappearance of the visual purple. Observations with a small screen and electric spark showed that the moment the spark flashed out there appeared on the screen a bright light rapidly increasing in in-

tensity and then fading away in about the same time. While increasing the light had the same color as the screen, but while decreasing the opposite color. A third phase followed, of much longer duration, when the light was reddish-brown, and while this lasted there was anaesthesia for objective light, such as that given off by luminous paint. This third phase corresponds with the after-images which arise by long-continued looking at a bright object and its projection on a white surface. This succession of light and dark in after-images is also seen on looking at a feeble light in a darkened room when the light slowly fades and disappears, but with the slightest movement of the eye it reappears as the light then falls on a fresh part of the retina; but if all movement of the eye be avoided the light after disappearing returns slowly to its former brightness, then again fades, so that a continual slow succession of light and darkness can be observed. This is regarded as due to a reciprocal effect of adjoining parts of the retina on each other, through a modification of the visual substance which undergoes an alternate assimilation and dissimilation.

Several candidates have already declared themselves for the vacancies in the Medical Council. Dr. Glover will again come forward and will doubtless be re-elected, so that two new members have to be chosen.

Professor Curnow, on retiring from the office of dean of the Medical Faculty after thirteen years' service, has been presented by his old pupils with a handsome testimonial.

Dr. William Cholmeley died on the 18th ult., aged seventy-three. He was editor of the extinct *Medical Times and Gazette* from 1873 to 1883, but his chief work was at the Great Northern Central Hospital, of which he was one of the founders and one of its most ardent supporters for the last thirty-eight years, during which time he enjoyed the respect and esteem of all his colleagues. Last year the Ladies' Association of the hospital endowed a bed, "In loving appreciation of many years' devoted and unselfish labor rendered by Dr. Cholmeley to the sick and suffering, both as physician to the hospital, of which he was one of the founders, and as honorary treasurer to the Ladies' Association."

METHODS OF ESTIMATING THE HEIGHT FROM PARTS OF THE SKELETON—A CORRECTION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: A paper with the above title which I had previously read before the Association of Anatomists was printed in the *MEDICAL RECORD* of September 8, 1894. In looking it over to-day for a special purpose I found a serious blunder that I feel it my duty to correct at once, though it is sufficiently evident to the careful reader. In treating of cases in which certain parts may be wanting, as for instance the pelvis, I gave a method of estimating the height of the promontory from the top of the great trochanter. I had previously stated that from my observations the height of the promontory above the symphysis is about 9.5 cm. in man and 10.5 cm. in woman. I then continued: "I find from measurements before dissection from one hundred and eighteen male and thirty-seven female white bodies, that in the males the trochanter is on the average 1.1 cm. higher than the symphysis, and 3 mm. in females. Having in view the greater height of the promontory above the symphysis in women, we may without serious error reckon that the promontory is 10.5 cm. above the trochanter in either sex." It is perfectly plain that if the symphysis and the promontory are nearer in man, and if also the trochanter is higher in relation to the pubes, the distance from the

trochanter to the promontory must be less in man than in woman, the difference being on the average nearly 2 cm.

It is needless probably to add that such methods are to be used with great discretion.

THOMAS DWIGHT, M.D.

HARVARD MEDICAL SCHOOL, July 10, 1896.

New Instruments.

A FOLDING OPHTHALMOMETER.

BY J. EDWARD GILES, M.D.,

NEW YORK.

A DEFECT in the ophthalmometer of Javal is that in its present form it is not portable and therefore cannot easily be used away from the office. To remedy this defect certain modifications of the Javal instrument were designed by Dr. E. A. Chapman and myself, and the mechanical execution of the work was carried out by Messrs. Fox & Stendicke, of New York, some of whose ideas are also embodied.

The instrument when set up appears like the Javal instrument in all points, except that the disc is cut out below the telescope sufficiently to allow it to be raised and lifted off by loosening a screw. The disc is cut vertically and hinged so that it can be folded and placed in the cover of the case, as shown in the engraving. The arc with the wires is removed by loosening a thumbscrew; the telescope is removed from the standard by unscrewing, and the standard and

headrest are each removed from the base by thumbscrews. After being taken apart the whole, with the arc and burners and reflectors, packs in a case the size of a large dress-suit case.

This instrument is provided with a gas burner, with the idea that it may have to be used where electric lights are unavailable. The Welsbach burner may be used, as this gives a light almost as good as the electric light.

The instrument is somewhat heavy, but the weight could be reduced by dispensing with the heavy disc and substituting a black cloth upon a wire frame as a background for the mires, and using a wooden base in place of the heavy brass and iron base. This modification of the instrument will be appreciated by those who for any reason have to examine patients away from the office, even though the occasion for such use may not frequently occur.

105 EAST TWENTY-SECOND STREET.

NEW SNARES FOR POST-NASAL AND INTRA-NASAL SURGICAL OPERATIONS.

By J. E. SCHADLE, M.D.,

ST. PAUL, MINN.

FIG. 1 is a snare designed for post-nasal operations, and represents a modification of the Dr. Jonathan Wright snare. The ratchet mechanism is practically the same as in the Wright snare, but has much stronger

FIG. 1.

cappings (*i* and *z*) to work the ratchet. In fact, the whole instrument is much stronger and heavier, and for this reason is adapted to snaring fibroids of the naso-pharynx, for which purpose it has been devised.

Either No. 5 or No. 7 piano wire can be used with this instrument. The wire fastener (*d*) consists of a screw cap (*e*, the articulating surface of which is traversed by deep longitudinal grooves which fit into counter grooves in the end of the shaft when the cap is screwed down, the ends of the wire to be fastened passing between and at right angles to these grooves.

The instrument is also armed with a tempered steel lance (*j*) with a curved end. This runs through bands on top of the wire carrier, for the purpose of transfixing the growth if so desired, and is shot into place by means of a thumb lever (*m*), worked by the same hand that is holding the snare. It has also a windlass arrangement (*g*) just in front of the wire fastener, which is adapted to help out the ratchet and facilitate either a fast or a slow snaring. After repeated trials and alterations the post-nasal curve, as seen in the figure, was perfected.

This modification is also particularly adapted to the removal of adenoid vegetations. There can be but little doubt, in spite of what has been written, that the snare is much more satisfactory in these cases than the curette or post-nasal cutting forceps, when the lymphoid mass is of any size.

Fig. 2 represents a snare constructed for intranasal work. The wire carrier is made a double cannula that will carry the transfixing dart or wire in either chamber, so that a right- or left-handed snaring can be done with the same instrument. The wire carrier is of a size that can be passed with ease, being but little larger in calibre than an ordinary Eustachian catheter. The wire fastener works on the same principle as the one described above, only it is at the side rather than the end of the tube. By means of the movable cannula at the proximal end to which the wire is fastened, and of the windlass, this snare adapts itself to slow or rapid snaring.

Through the courtesy and skilful workmanship of George Tiemann & Co., New York City, it was made possible to bring the construction of these instruments to the present degree of perfection.

A NEW STONE SEARCHER.

By LUCIEN LOFTON, M.D.

ATLANTA, GA.

In presenting to the medical profession an instrument which I consider to fill a long-felt want in genito-urinary work, I would most respectfully ask a careful trial in order to determine its practicability, its simplicity, and its usefulness. As shown by the cut, which has been kindly furnished by Messrs. Tiemann & Co., of New York, the searcher can readily be attached to any of the newer forms of stethoscopes. The searcher consists of a hollow sound, having two eyes or openings in the curve and an outlet with plug near the handle, a hollow corrugated metal handle terminating in a solid screw receiving the hard-rubber metal-lined connecting piece, to the two

FIG. 2.

branches of which the soft-rubber tubes of the stethoscope are attached.

Foreign bodies introduced into the bladder are liable to take on dead epithelium, mucus, and other debris, and in consequence thereby become enveloped in a coat of material which is next to impossible to recognize from the mucosa by the old method of sounding. This searcher is simple in its construction and is sensitive to any impression made upon it, be it in direct contact with or sliding over a foreign body. The slightest metallic vibration, whether shielded or not, will be transmitted with unwavering evidence through the instrument. The searcher will not transmit the blow made by striking the lining membrane of the bladder during manipulation.

Should a foreign body be encountered in any portion of the urethral tract, the motion made in sliding the sound back and forth will give a distinct metallic, scraping noise. It is therefore advised that the searcher should be adjusted to the ears prior to passing it into the urethra. It matters not how small stones may be, or whether they lie in the urethral

Lofton's New Stone Searcher.

tract or in the bladder, contact with this searcher will reveal at once their presence.

Strictures of a sufficient calibre to allow the sound to pass will give a soft grating noise. It is a peculiar vibration and will not be mistaken for the noise caused by contact with any true foreign substance.

Two sizes of the searcher are made—one for adults, and one for infants and children, the same ear attachment, however, answering for both.

Upon the same principle, with œsophageal bougies penetrated by a steel wire with a metallic bulb at the distal end and the ear attachment at the other fastened with a screw head, the stomach may be searched for foreign bodies. The bullet probe may be utilized in a similar manner, the distinction being, as a rule, easily made between bone and bullet.

SAFETY ATTACHMENT FOR THERMOMETERS.

BY ORRIN C. ANDRE,

WAVERLY, O.

THERE is perhaps nothing more calculated to cause the average physician to utter exclamations that would be hardly proper under certain surroundings than to have his clinical thermometer drop from his pocket with the usual result. To obviate this difficulty I would call your attention to a little device which has proven both convenient and efficient. As shown in the accompanying cut, it consists of a piece of soft rubber of good quality, with an opening of the proper size to admit the usual hard-rubber thermometer case; attached to one side is a small eyelet, by which it may be either sewed or fastened with a small safety pin, just at the upper and inner corner of the vest pocket.

After placing the thermometer in the pocket it requires but a second to pull the loop over the top, where it is secure until again needed. These "thermometer safety attachments" are made by Messrs. George Tiemann & Co., New York.

'SKIASCOPIC RACK.

BY FRANK D. SKEEL, M.D.,

NEW YORK.

THE rack here shown was designed to take the place of a more expensive apparatus. It is so constructed that any lenses from the trial case may be inserted in the clips, and a sliding clip is provided to carry an additional lens for combinations. In use it is held

by the patient in front of the eye, the examiner directing the patient to move it upward or downward as the case may require. In this manner a very rapid retinoscopic examination can be made.

This instrument was made for me by Messrs. Fox & Stendicke, New York City.

14 EAST TWENTY-THIRD STREET.

Abscess of the Breast.—It is now known that abscess of the breast is the result of an infection, generally through a fissure or abrasion of the nipple or areola. The staphylococcus, especially the staphylococcus aureus, is the most common agent. The vascularity of the breast during lactation and the presence of an animal fluid afford favorable conditions, and any breach of the surface about the nipples gives the microbe ready access. The infection is through the lymphatic channels. Dr. Shields (*Lancet*) alludes to the possibility of organisms entering along the milk ducts themselves. Organisms may enter the sebaceous glands of the skin and produce boils or pustules, and as the breast is only a highly developed sebaceous gland there is no reason why infection might not occur through the nipple and milk ducts. — *Boston Medical and Surgical Journal*, June 11, 1896.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 18, 1896:

Measles.....	145	19
Diphtheria.....	214	23
Small-pox.....	0	0

The Physiology and Function of Hair.—At a late meeting of the Medical Society of Vienna, writes the correspondent of the *Medical Press*, Professor Exner gave a lengthy review of the different opinions entertained by historic authors on the growth of hair. Many volumes had, he said, been written on this momentous subject, yet the function of this integumentary structure is not to be found in one single text-book. Schein, of this city, has advanced the idea of hair being the outcome of stunted growth of the tissues and that where activity abounds hair always disappears on the surface. Within the last twenty years the subject has been much discussed in connection with the presumed transformation of man from monkey. Climate and sunshine have been deduced by Darwin. Even taste by selection has not been without its devotees in ascribing the cause of depilation to the human race, while Maurer has more recently assigned hair to be the outcome of more sentient structures, as testified to in fish and reptiles, in which hairs connected with sensitive papillæ of nerve structure are found. In animals higher in the scale we find the rudiments of these appendages, which have become obsolete through disuse. The hair appears yet on the head of the human fœtus, which would show that the time was too

short for denuding the body, or that it yet serves some useful end. Exner is in favor of a sensory function, which Mises has undertaken to demonstrate histologically by the nerve apparatus of the cilia, which

sensory connection Jaubert, of Paris, has confirmed as a protection for the eye. The hair of the eyebrows, as well as the fine hair over the whole body, acts in a similar manner. The hair of the armpits and genitals is evidently to prevent chafing as described by the Grecian writers. The thick coat on animals of hair or wool has an electrical property beside the covering it provides for inclement weather, the hair being positive, while the fine wool is negative. Both are bad conductors of heat, and thus moderate the heat of the body by retaining the physiological product of combustion, at the same time moderating the transmission of cold or hot rays from the existing climate. The ornamental function of Darwin was no unimportant feature, as the beard of man and the long hair of woman have still an adorning influence.

Sexual Hygiene.—From an article on this subject by Dr. Thompson, published in the *Medical Century*, June 1, 1896, we take the following: "The tendency of our time, particularly the prevalent contempt for religion, makes chastity more difficult for every one, and the invert suffers far more from this than others. Instead of debasing the honorable invert by making him run after prostitutes and subsequently become the unfortunate husband of a less fortunate wife, and the

father of children who suffer as much as he or more, the attempt should be made to occupy and interest him, to show him the horizons he can attain by dint of will. If chastity were a virtue in better favor, I should recommend it to physicians as a more effective remedy than to send the invert to 'puella' to prepare him for marriage and paternity. It would be better not to increase the number of husbands and fathers who are inverts or pervers. As for the invert who wishes to marry in order to have children his desire is almost criminal. If he marries for social convenience, to reinstate himself or to please his family, he should marry a woman older than himself, a woman of the world, who understands everything and accepts the situation. Those familiar with the confessions of inverts, and a marvellous lot are correlated in the works of Krafft-Ebing, will see that in the same ratio as their sexual feelings are distorted so is their conception of themselves, their surroundings, and everything else in the world. The superior invert has no right to think he is born out of his epoch or his country. Even the orient to-day (where pederasty is practised without difficulty) would not offer him the intellectual pleasures to which he is accustomed, music, the theatre, etc. He would see with a smile that most of the new Greeks would have been considered too sickly or too generally malformed to be reared by the Spartans. He will see with more or less courage that the satisfaction of the sexual appetite is not, and cannot be, the *sine qua non* of existence to a modern man. Too long has the general practitioner given this subject over into the hands of a few specialists who see almost entirely the extreme cases, so that there is a great dearth of literature relative to its development and prophylaxis. To quote Nordau, specialists have failed to understand their duty. It is time for them to come to the front; it is no doubt meritorious to indurate sections of the spinal cord in chronic acid, and tint them in neutrophylic solution, but this should not exhaust them. Neither is it sufficient that they should give a few lectures to jurists, and publish observations in technical journals. Let them speak to the masses of cultured persons who are neither physicians nor learned in law. Let them enlighten them in general publications and accessible conferences, concerning the leading facts in mental therapeutics. If civic authorities deem it necessary to consult us with reference to bodily hygiene and sanitation, should we not have some jurisdiction over that more important and far-reaching field, the sanitation of the mind? Then the baleful influences of the Ibsens, Zolas, and Rousseaus might be curtailed. 'Then 'Heavenly Twins,' 'Jude the Obscure,' 'Trilby,' and the 'Woman Who Did' will cease to be the centre of a gushing, hysterical, psychoneuropathic circle and its followers, the faddists who follow because they have not the ability for independent thought."

Light Cures.—Some one in one of the lower provinces of Austria has evolved the idea that light is the great health-giving and life-preserving agent, and that all that is necessary to cure most diseases is to expose the body to its action. He has accordingly founded an establishment where this remedy can be applied without contravening the rules of society. The institute is open during the summer months. There are two large enclosures, divided by a high wall, so as to separate the sexes. The method involves the exposure of the absolutely naked body to sunlight and air, irrespective of atmospheric vicissitudes. The patients are enjoined to pass the greater part of the day in a state of nudity, and little by little they are expected to develop such a measure of resistance as will enable them to withstand all changes of temperature and humidity. When the sun is high the patients lie

around on the dry turf or on planks exposed to the full force of the summer sun for periods varying from fifteen minutes to an hour. One effect of the exposure is to provoke profuse perspiration, but in newcomers more or less superficial inflammation of the skin not infrequently follows. It is not only the sunlight that is employed, for the treatment involves exposure to rain and wind as well.

Observations on the Exhalation of Carbonic Acid.—

Prof. Ugolino Mosso, of Turin, has tested the breathing of soldiers during an expedition up Monte Rosa, and found that the quantity of carbonic acid exhaled by a man at a height of twenty thousand feet or so differs very slightly from what it is at the sea level or near it. The professor has also subjected himself to a rarefied atmosphere in the Physiological Institution at Turin, and found that when the pressure in the air was still thirty-four centimetres (about seven inches) of mercury, he felt no inconvenience, but when it was reduced to thirty centimetres (about six inches) he felt a great want of breath, and became unfit to make observations.

Books Received.

While the MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

USES OF THE STOMACH.¹

By GEORGE D. BLEYTHING, M.D.,

NEW YORK.

THE influence of the stomach upon the history of the world is incalculable. What military heroes and explorers have accomplished must have been left undone if their fiery zeal and deeds of high emprise had been quenched by dyspepsia.

Perhaps one person out of each five thousand human beings has an intelligent idea of the fact of a stomach and also puts it to its proper use.

Healthy mind in a healthy body must mean primarily a stomach performing its functions of transformation and supply to the body—of sustenance—and this excludes gastrectasis, auto-intoxication, changed mucosa, diminished secretion of gastric juice, atrophied or hypertrophied muscular coat—all of which are inimical to sustentation of body.

Unintelligent parents of high and low degree, sometimes of their own and sometimes by their medical man's culpability, take the option of destroying the health and comfort and maiming the powers of the future man or woman; while in other cases the man and woman with a stomach well used in early life take the onus of destruction upon themselves.

The mother who will not suckle her infant has the first opportunity of deciding if that individual stomach shall be put to its normal use or if it shall be condemned to a series of experiments with concoctions. The experimental uses are various, as our profession has a habit of insistence upon its successive schemes, each being as it is reached the ultimate, and no favor is shown to the unfortunate who has not the last fashion.

The seriousness with which we all take up contradictions and agree to them suggests the successive mimicries of children—as if we had said "Let's play school," or, "Let's play bears," and at once we are hypnotized into the belief in our transformations.

The fashion rages for milk uncooked, milk cooked, milk sterilized, milk pasteurized, milk modified, and we don't laugh while we play the games, nor yet when all are set aside for the manufacturing chemists' products, which it were a weariness to the flesh to enumerate.

Still through it all go on the unwearied laborers who with patience have brought us to many verities, which will be passed only as stepping stones in our advance.

In 1875 Ewald's flexible tube, in 1883 (I think) Oser's lavage and experimental meal were definite and good—and, while permitting new discussions of the diagnostic value of lactic and hydrochloric acids, furnished improved implements for exploration. In the use of the stomach we may consider what may be done in our present state of knowledge to save the gastric sinner from judgment to come. No doubt many a life is signed away, as already intimated, by the misuse of

the stomach in infancy. The child that should be suckled is given as a substitute for the natural fountain a bottle with a rubber nipple, and as much of assorted bacteria as environment furnishes, together with such chemicals as he can get by suction from the nipple and more or less of a supply of the products of milk degeneration not washed from the rubber nipple and bottle after use. Then of the nutritive fluid itself: we know that while many children exist through their probation and seem indeed to thrive, many succumb or are insured an after-life of indigestion, malnutrition, and, as sequelæ, anæmia, neuræmia, neurasthenia, arthritis, or tuberculosis.

The viscus under discussion when in possession of childhood advanced beyond dentition has, in addition to mistakes of treatment by parents and nurses, the abuse that its own carnal desires can confer. Among children of the so-called working classes with few exceptions the choice is rarely of any diet but that which the children elect. The mentor has no judgment to exercise. In a large number of families who would resent being classed with persons lacking judgment, and who are of the plutocratic if not the aristocratic circle, no more competent authority than a child's appetite is recognized in choice of food.

Many a deserving doctor's revenue would be curtailed by a reform. I recollect the late Dr. Agnew asking me to sit down at his side at his Manhattan Infirmary eye class years ago, and listen to the answers given by the mothers of the children with different forms of eye disorder—ulcers of the cornea, tarsal and kindred disturbances of nutrition—when interrogated as to "what do you feed the child?" The answer was invariably: "Oh, whatever is on the table." We all have had the range of disorders of malnutrition to treat of which perverted abuse of the stomach was the ultimate cause. I remember an only son of a rich family who had a most obstinate eczema, which I found to yield readily to treatment when the nine-year-old patient gave up coffee and his claret for dinner. When a certain class of parents aims to be logical in a child's feeding, they reason that the food fit for a laboring man or the sumptuous fare of a gourmand is what the child needs to give him the muscle of the one or the fat of the other.

When the child reaches the stage of bolting meals, green apples, etc., he usually takes so much exercise and gets such an amount of fresh air, that his condition is ameliorated up to the time when cigarettes and cocktails come into the field.

In these days a boy of sixteen not fully conscious of his ability to direct his affairs better than his parents could advise him to do is a milksop and out of the count, and so there is taken up the abuse of the stomach, as a settled plan of action. A hastily bolted breakfast with coffee, a cigarette or two on the way to school, pie or sandwich and beer for midday meal, and anything bad that the fertile ingenuity of a French, Irish, or African cook can produce for a seven o'clock dinner, are the rule with the boy and very likely the girl varies her menu only by taking her cigarette in her bedroom.

We must agree that adults do not apply their matured wisdom to produce for themselves a better use of stom-

¹ Read before the Lenox Medical Society.

ach. If any meal is fit for physiological uses in our day, it is breakfast, at which we are more or less penitential and prepared by last night's dinner for a simple meal.

Fruits, a cereal, an egg or fish, and bread constitute perhaps a typical American breakfast and should be digested and discharged from the stomach in two and a half hours, and a man or woman not exhausted by a dinner that was almost a debauch eats it; but how many patients say to us: "I never take anything at breakfast but a cup of coffee"? Especially is this true of women and young girls. I always order for such, corset loosened and forced feeding—an egg beaten in a glass of milk for breakfast until the victim will take a chop in place of it.

The only purpose in reviewing all this is to present as strongly as possible that as a rule we are engaged one and all in ignoring the physiological uses of the stomach and making it a receptacle for whatever tickles the palate on the way. Hot, cold, sweet, acid, peppery, oily, in varied succession shock the poor organ into a state which the newly discovered Roentgen rays may some time picture for us. Think of a man in training for a contest in which physical well-being is important, eating almost any of those pathological preparations which a proper dinner menu holds forth. Think of pickles, salads, sauces, pasties and pastries, *pâté de foie gras* and ices, with a lot of wines and liquor poured over, in a viscus lined with most delicate secreting membrane and the illogical expectation of health, strength, and long life ensuing. The athlete in training who indulged in our usual diet would be mobbed by the men who had backed him for a match of strength and endurance.

We have to do professionally with the state of stomach that this misuse brings about, but of course we have likewise to do with its prevention. Prophylactics is equally with therapeutics our province.

In the normal use of the stomach we have to observe albumin and starch from ingestion to dismissal thus: Mastication breaks up the albuminous body for the action of digestive ferment, pepsin. The more important varieties are egg, plant albumin, fibrin, casein, and these become propeptone and peptone. Intermediate are the albumoses, of which syntonin is conspicuous as the product of neutralization.

If gastric juice containing pepsin and hydrochloric acid be allowed to act on albumin these modifications of albumin result—the more or less perfect result indicating the intensity of the digestive processes. When removed and tested by heat the stomach contents coagulate if albumin or syntonin be present, or both. If not shown to be present by coagulation, we may find peptone.

Boas says propeptone is absent in the digestion of meat, and we do not know if it be a necessary preliminary to peptone, only it is a very frequent transformation product in digestion of albumin by pepsin and hydrochloric acid.

The amount present in the digestion of a mixed diet bears a relation to the energy of digestion. The striking feature of the pepsin and acid digestion of solid albumin is the rapidity of liquefaction.

Starch digestion is accomplished rapidly in the mouth largely by the salivary ferment ptyalin, and is then continued in the stomach. This is checked in acid fluids of course, the starch going through intermediate forms, dextrose and maltose, but is continued in the intestines.

Some portion of these prepared substances are absorbed by the stomach. That the organ has absorptive powers Ewald shows by iodide-of-potassium test, iodine showing in the saliva in ten or fifteen minutes if the digestion and absorption are normal. Still the function of the stomach is not absorption, this being inci-

dental, and upon the muscular power of the stomach to discharge its contents depends the continuance of healthful digestion and of a normal stomach. Accumulation of food promotes fermentation, putrefaction, and distention of the stomach. In turn a distended stomach becomes a hypertrophied stomach, or its walls lose motility and the contents still further accumulate and breed ptomains.

Bouchard names among poisons generated by decomposition of food butyric, acetic, and lactic acids, leucin, tyrosin, phenol, indol, skatol, etc., and Emile Boix has written a work on the acid poisons in liver dyspepsia. These poisons are not to be confounded with the ptomains and bacteria necessary to digestion. Pasteur advanced the hypothesis that vitality depends upon bacteria for its continuance, but did not refer to the organic acids of fermentation.

Boix places the liver in charge of these poisonous substances and considers the action of the liver cells in their destruction as parallel to the action of white blood corpuscles as phagocytes.

Hepatic congestion is caused by too large an influx of the products of indigestion, alcohol being also named among these chief—and Bouchard associates tumefaction of the liver with gastrectasis or dilated stomach.

Now it is stated by Bouchard and others that a marked cause of hypertrophy and hardness of the liver is the presence of these acids of fermentation. Likewise Bouchard and Boix give arthritism as a hereditary precursor of sclerogenous liver. Of five of his reported cases four had a history of arthritic heredity.

Hares fed with bran saturated with food-fermentation acids developed hepatic cirrhosis. A hare fed for two months with butyric acid died emaciated, and post-mortem examination shewed cirrhosis. Acetic acid gave still more marked results.

Likewise Boix's experiments with cultures of colon bacillus and toxins resulted in sclerosis of portal spaces.

Dr. Alexander Haig has made the most exhaustive study of the excretion of uric acid and of its relation to urea, and whether it establishes his theory of rheumatism and its uric-acid origin or not, the great number of facts with their logical presentation is a work to distinguish a scientist even in these days of brilliant developments.

The gentlemen of the Lenox may have espoused Dr. Haig's uric-acid theory or the at present highly popular bacterial theory. I desire to be in harmony with all parties, and believe the acid may in some way be proven a ptomain or result of bacterial toxin. We have Fraenkel as authority that some of the substances recognized as bacterial products are chemical bodies well known and exactly defined as to composition. I confess to having no logic to present with my hypothesis, but let it stand under that name. Haig proves that uric acid bears always a definite relation to urea, 1-35, and when in excess of this proportion arterial tension is increased and the discharge of urine diminished. In his experience sodium salicylate assists in reducing that excess, and this accounts for its efficacy in treatment of rheumatism. This has its bearing upon stomach digestion, as acid urine bears a relation to stomach disturbances and there is a connection between the acid of the gastric juice and that of the urine. The proportion should be lower after taking food. Lavage or whatever reduces acid of stomach reduces acid of urine. Ingestion of milk raises acid of urine, by reason of lactic acid.

Haig has studied the variations of pulse tension under different drugs, at different hours and different pathological conditions, with sphygmograph and stethoscope, has recorded the curves of uric-acid excretion

under administration of salicylates and other drugs and has run a parallel between the excretion of uric acid and the exacerbations or remissions of rheumatism; indeed his work in this direction has been so thorough that nothing but admiration and gratitude can be felt for his reports. He says: "If uric acid really influences the circulation to the extent which I have been led to believe it does, it follows that uric acid really dominates the function of nutrition and structure of the human body to an extent which has not been dreamed of in our philosophy, and may direct the development and life history of every tissue." This sounds very extravagant, and will much more than cover the claim of Bouchard and Boix of an arthritic diathesis, associated with a cirrhotic liver and a stomach with impaired muscular motility, as a chain of consecutive links.

Alcohol produces, according to the demonstrations of Frerichs and others, the effect upon the liver that the fermentation acids do. Haig declares the ingestion of meat to more than predispose by its digestive products to a uric-acid diathesis and recommends for safety a vegetable diet to all.

In my own practice it is my habit with dyspeptics and also with victims of more serious stomach disorders and habitually constipated subjects, to insist upon the taking of two quarts of water free from putrefactive matters daily, whether hot or cold depends upon circumstances.

I have felt satisfied with the result of this regimen in migraine of long standing and I rely upon pure water as the chief remedy for dysentery. It seems to me logical that a people who employ their stomachs as catch-alls of substances capable of putrefaction, till the stomach is distended, in a state of atony, and almost never empty because of loss of motility, must need a flushing of the stomach and intestinal track and a removal from the bowels as well of the breeding-matter of bacilli and toxins, and this can be more certainly effected in a semi-liquid state. Likewise, if the cause of migraine, epilepsy, and arthritis is, as Haig believes, uric acid, or if other products of fermentation, lactic and acetic acid, cause irritation of the stomach and liver, and a cirrhosis as readily as does alcohol, it is better that the acids be well diluted with water, as in this condition they are better fitted for excretion.

The examination of the abdomen by percussion gives no outlines of the normal stomach, as all is covered by the border of the ribs. Distended with water or gas, the splash and clapote are inferior to percussion in locating the organ, but tell if the viscus is empty.

The value of the experiments is in measuring the motility of the organ, which is usually diminished in ratio to its dilatation.

This function of motility is to the last degree essential to comfort and benefit to indigestion. The work done in the stomach not being final, when this stage is accomplished the power of propulsion should be equal to sending the chyme through the pylorus to complete metabolism and to give the stomach rest.

Dr. Van Pelt, of Boston, has reported some cases followed out upon the line of Haig, making the same analysis tests for urea, uric acid, and acidity, together with observation of arterial tension.

As not all of these cases were frankly rheumatism, it is to be supposed that Dr. Van Pelt agreed with Haig upon the universality of effect of uric acid and its consequent arterial disturbance, and followed the cases with treatment to establish alkalinity of the blood and thereby the solution and excretion of uric acid.

The first reported case was of curious attacks in the early part of the day, which began by a sense of pressure at the top of the head, drowsiness, and a semi-conscious

state lasting three or four hours. Upon recovery the eyelids were swollen, the face was ashen. Since the attacks memory had failed, there was mental and physical depression, nervousness, and insomnia. She was troubled with acne. She had had malaria as a child, but examination for plasmodium had no result. Examination of urine showed:

Amount in cubic centimetres.....	1,000
Specific gravity.....	1.015
Acidity, in grains of hydrochloric acid.....	1.70
Urea, in grains.....	10
Uric acid, in grains.....	.90
Relation between two latter, 1-21.	

Sodium salicylate, twenty grains every four hours, resulted in magical relief.

She had before slept only with large doses of trional. After twenty-four hours' treatment she slept without a hypnotic and the urinalysis showed in that time a drop in the relation of uric acid and urea to 1-16.

Although pinning my faith to the uric-acid theory, I have but two cases to report in which I can vindicate my belief.

The first is a case of neurasthenia which I have had for twelve years under surveillance. When I first saw the lady she came as a patient and her history was of neurotic inheritance. Her grandfather was a distinguished architect, her father a literary man of overstrung, emotional nature.

The daughter was of slender physique, poetical temperament, and a writer by vocation. At this time she was quite broken down with overwork. She suffered always with headache and at irregular intervals with exacerbations of blinding intensity, for a day with sick stomach and then with a day of prostration. I made an effort at the outset to put the patient in a better state of stomach, but she was so sensitive to criticism that a prohibitory diet resulted in her eating nothing. In those days I was alarmed by this and let her eat what she would, and though the quantity eaten was not large, with restrictions removed it was of most substantial diet, including meat three times a day. I next had the eyes examined by an oculist, who found astigmatism and that the focus of two eyes differed in distance. This was remedied by glasses and some improvement of headache ensued, but I was compelled to change habits, occupation, prescribe travel, etc., and also ran the round of the whole pharmacopœia, trying finally, with other things, Taylor's passive-movement cure.

In the course of six years of attendance I had sympathy and patience sorely tried. I had decided that independently of the eye strain her general malaise of neurasthenia often was called headache and that the paroxysms of intense pain had ceased.

Overfatigue, however, brought on severe nervous disturbance, sometimes upsetting the stomach. This made it impossible for me to induce the patient to try exercise, except in a martyr spirit of obediently walking to the stake, which insured a failure. Massage she refused because it was repugnant, and the first escape from this difficulty was by Taylor's mechanical movement, to which she always went with streaming eyes. In spite of this repugnance, however, the patient could sleep without hypnotics for the first time with this treatment, and, having paved the way and gradually led up during years of attendance, I arrived at the subject of meat eating without causing shock and accomplished a diminution to one meat meal daily. I found by being called when later the crisis of headaches and malaise recurred that, though she was a person of the daintiest tastes and personal habits, there was at this time an explosion, so to speak, of bad-smelling sweat, with nervous hypersensitiveness, headache, and often vomiting. Of course in

ten years' attendance I had informed myself upon the state of the kidneys and had found no organic disorder. The urine was at some times loaded with urates, sometimes with phosphates, but never showed albumin and casts.

I came two years ago to the conclusion that some gradual accumulation blew off at these crises and that uric acid might be the offense. Various alkalies failed of anything but upsetting the stomach, when I stumbled upon salicylate of sodium, with the idea of there being a rheumatic element in the headache. To my amazement, after two days the symptoms were alleviated in every regard, so that the patient spoke of feeling so light without the headache. General improvement continued and the patient, while not of course robust, can now do all that a woman of her physique usually can, and we are discussing the propriety of her appearance on a wheel.

I regret that my case makes so bad a showing beside the others noticed in which scientific data are given. I reached my conclusion in a stumbling manner, and my cure was empirical; but I am in possession of the knowledge that it brought me and it verifies to me more concrete work and theories and gives encouragement for the future. Only a doctor with a neurotic patient who sticks to him for twelve years knows what the mental state is that follows such denouement.

I have had cases of migraine which have not been so complicated but have been troublesome, and they have been improved or else the patients have got tired of me and have gone to some one else, or settled down to endurance. I have one patient, a business man of thirty-five, who, though a stoutly-built muscular man, has from childhood suffered periodical attacks of migraine. I gave him two years ago the benefit of my aqueous-solution treatment and reduced his meat eating.

He has since had the attacks at longer intervals and in a modified form. I did not see him for a number of months, until about three months ago, when he returned from abroad. I found he so far believed in the relief of the water drinking that he usually kept up to near his two quarts, and I then ordered ten grains of salicylate of sodium. Curiously, it gave him a headache. Following Haig's advice for rheumatism, I gave him iodide of potassium for a week and then returned to a double dose of the salicylate of sodium (gr. xx., t. i. d.), and so far he has had no migraine.

We come back to the stomach as the source of difficulty: its misuse and its retaliation. Indeed, no old case of dilatation, atony, and retention of putrefactive substances for hours in an almost never empty stomach can be lived with at peace.

1008 MADISON AVENUE, May, 1896.

Management of Cases Immediately Following Operations.—Sir Thornley Stoper (*British Medical Journal*) writes as follows: "If I may reduce to formulae the matters I have referred to, I would put them thus: (1) That the tendency to prolong operations must be carefully guarded against, as it is a grave cause of danger. (2) That in the treatment of shock and vomiting following operation we get no help from the stomach, and must rely on the rectum as its substitute. (3) That heat, alcohol, and opiates are our best remedies; and that the latter are well borne, and must be intelligently used to their full effect. (4) That drugs of the class ordinarily used to check vomiting are of little or no use in the cases under consideration. (5) That ice does not relieve thirst, and does harm by introducing water into the stomach and so provoking vomiting."

THE CLINICAL HISTORY AND POST-MORTEM APPEARANCE OF A CASE OF CORTICAL EMBOLUS (RED SOFTENING).

By H. A. TOMLINSON, M.D., SUPERINTENDENT,

G. A. CHILGREN, M.D., ASSISTANT SUPERINTENDENT,

ST. PETER STATE HOSPITAL, ST. PETER, MINN.

THE following case is of especial interest because in our experience among the insane this is the first opportunity that has presented itself for the careful study of the clinical features and post-mortem appearance of a case of embolus with resulting thrombosis, in which death has occurred sufficiently early to prevent the obscuration of the distinctive degenerative changes in the cortical cell by the products of general disintegration.

We also think it worthy of note that the changes shown verify Berkeley's statement that degeneration is the same, no matter what the cause of it may be; besides, this being a natural instead of an artificially produced change, adds that much to the value of the case as illustrating cell degeneration. Another and perhaps the most important point illustrated by this case is the apparent proof furnished that degeneration in the cell really results from failure of nutrition, and that the so-called causes are practically only antecedents, having a common effect.

M. B.—, widow, native of Sweden, aged sixty-five years, was admitted to this hospital, July 31, 1895, with the following history: Two weeks before she became much depressed and complained of having a headache continually. She said she could get nothing to eat and was starving, and that she had committed a great crime and had something on her mind that she wished to tell. She always refused any food offered her, and did not succeed in telling what she apparently wished to.

She had a history of having been insane about twenty years ago, and of always having had a violent temper. No family history could be obtained. When admitted her temperature was 100.2° F.; pulse, 90, of fair volume and regular; respiration, 18 a minute. She was well nourished and appeared to be strong. Examination of the heart and lungs showed nothing abnormal. Her urine had a specific gravity of 1.039, was acid, of a dark yellow color, and contained two per cent. of sugar and some granular casts. There was slight asymmetry of the face; the pupils were equal in size, four millimetres, and reacted readily to light but not to accommodation. There was no evidence of paresis in the limbs. The knee jerk was equal on the two sides and about normal. Clonus was absent. There was marked coarse tremor of the tongue, her speech was slow and indistinct, and she appeared to have considerable difficulty in speaking. During the first week she was very restless and at times noisy, making various inarticulate sounds. She slept poorly and generally was restless at night. A marked intention tremor developed in the right upper and lower extremity. This was more marked in the upper extremity.

Second week: She is very stupid and is filthy in her habits. She does not attempt to feed herself, but eats fairly well when fed by the nurse. She is restless and often attempts to get up. She at times tries to bite the nurses. The right arm and leg are in a partially spastic condition, and she has but little control over them. When up she tries to walk by holding on to chairs, etc., but often falls.

Third week: The spastic condition of the right side continues and there is marked involvement of the left side, as shown by choreiform movements when motion is attempted. The pupils are unequal in size, the left being the larger. Both pupils react slightly to light.

Fourth week: She makes no effort to swallow when fed by the nurse, and when fed by means of stomach or nasal tube vomits immediately after the feeding. She lies in a semi-stupor condition, eyes closed, mouth open, tongue dry, pulse regular, 80 beats per minute. She perspires profusely. The extremities are spastic. Convulsive movements occur. Sometimes they are general, and then again they are confined to one limb or to one group of muscles. The pupils are equal in size, three millimetres, and do not react to light.

During the last three days of life the convulsive movements gradually disappeared, respiration became more labored, and the pulse weaker. The temperature did not rise above 102.6° F., and the highest pulse rate was 117.

Necropsy, made three hours after death: The skin was uncolored except in dependent parts, and there was no post-mortem staining. The head was well covered with light hair, not yet gray. The eyes were blue, the pupils moderately dilated and equal. The eyeballs were sunken and the lids fully closed over them. The superior central incisor teeth were exposed and protruded beyond the lips. The mammary glands were not atrophied, the lineæ albicantiæ numerous, and there was a brown pigmentation of the skin of the lower abdomen and of the iliac regions. Rigor mortis was present.

The general nutrition of the body was good, with large deposits of fat in the mammary region and in the abdominal walls. Muscular development was fair and the deposit of fat was not so pronounced in the limbs. There was atrophy of the dorsal interosseous muscles in both hands. There were areas of redness over each buttock and an area of extravasation over the upper and anterior portion of the right thigh, irregularly circular and about five centimetres in diameter; also extravasation showing finger marks on both arms.

The scalp externally was free from scars; internally it was adherent, especially at the vertex, and there was considerable deposit of fat.

The skull externally was free from scars, but there was a shallow depression corresponding to the sagittal suture. Internally the groove for the longitudinal sinus was shallow and sigmoid in shape, but the grooves for the vessels, even the most minute, were quite deeply excavated. The external table was thickened and there was a marked development of the diploe, especially in the frontal and occipital regions. There were numerous small Pacchionian depressions on either side of the median groove in the frontal and parietal bones. The dura was roughened anteriorly and adherent to the bone, shredding on removal, but its internal surface was smooth. The thickness of the membrane was increased, and its sinuses and vessels were partially filled with fluid blood.

There were one hundred and twenty cubic centimetres of cerebro-spinal fluid.

The pia-arachnoid was not adherent, its vessels were moderately injected, and, although there was no opacity, the membrane was gelatinous in appearance on its external surface, and there was deep staining in the sulci, especially in the frontal and motor region.

The brain weighed twelve hundred and twenty-one grams. At the base the blood-vessels were not thickened or hardened, but there was a small aneurismal distention at the bifurcation of the basilar artery. The cranial nerves were shrunken and tough. The island of Reil was shrunken in both hemispheres, and the convolutions surrounding it were retracted so that the insular and gray matter in the bottom of the fissure of Sylvius were exposed.

The corpus callosum was very short, and along its superior surface, in the median line, ran a fibrous cord, two millimetres in diameter, and apparently con-

tinuous with the pial covering of the corpus callosum. Over the convexity the convolutions were shrunken and the sulci gaped. The convolutions were simple in character over the whole convexity, the simplicity being most marked in the frontal and motor regions. On the right side the pre- and post-central as well as the Rolandic fissures were straight and well defined, but the Rolandic did not reach to the median fissure. On the left side the Rolandic fissure extended to the median fissure, but the pre-central was not so well defined, so that the ascending frontal and second frontal convolutions were confluent. The cortex over the motor region, in the fissure of Sylvius, and in the anterior portion of the parietal region on both sides was pinkish-red in color, quite in contrast to the rest of the brain. The substance of the centrum ovale was pale and slightly shrunken, but the puncta were well marked and dark blood oozed from them on section. The corpus callosum was shrunken from before backward, as was the fornix, and their substance was tough. The fifth ventricle was almost obliterated.

The lateral ventricles were reduced in size, and through the iter there was a membranous raphe, apparently continuous with the ependyma of the third ventricle, one millimetre in height and the same in thickness. There was no thickening or roughening of the ependyma in any part of the ventricles aside from this.

The gray substance of the cerebellum was pale and softened. The dentate bodies were well defined, and the white substance was not so shrunken as in the cerebrum.

The anterior mediastinum contained fat in layers in its lower portion; posteriorly the mediastinum was normal. There was no fluid in the pleural cavities, nor were there any adhesions.

The left lung weighed four hundred and thirty-nine grams, and there were slight adhesions between its lobes at their roots. There was a small area of hypostatic congestion in the external and superior portion of the lower lobe, and a small nodule, partially calcareous and measuring two millimetres, in the same region. Otherwise the lung was crepitant throughout.

The right lung weighed five hundred and eighty grams, and there were adhesions between its lobes, most resistant between the middle and upper lobes. In the superior portion of the lower lobe posteriorly there was an old fibrous scar, three centimetres wide, nine centimetres long. In this fibrous mass the outline of the lobules was partially retained. There was a considerable area of congestion in the apex, with free exudation of fluid on section of the smaller bronchi. The rest of the lung was crepitant.

The heart weighed three hundred and ninety-six grams, and its surface was thickly covered with fat, especially over the right side. There were calcareous crescents at the bases of two leaflets of the aortic valve, and a nodule of similar material in the other leaflet. The heart muscle was flabby, its cavities empty; the valves were competent.

The omentum was normal in length and position, but contained considerable fat, especially in its lower portion. The stomach showed no sign of disease, nor did the intestines, except that the colon contained scybala throughout its length.

The spleen weighed one hundred and thirteen grams. Its capsule was free, and the pulp was soft and friable.

The liver weighed thirteen hundred and eighty-five grams. Its capsule was adherent except over the left lobe, and there was adhesion of the right lobe to the peritoneum, posteriorly and superiorly, over a space eight centimetres in diameter. The lower border of the liver reached only to the margin of the seventh rib anteriorly. The substance of the right lobe was soft and friable, this condition starting from the point of

adhesion and spreading throughout almost the entire lobe. The gall bladder was full, contained two stones, each as large as a filbert, and its duct was patulous.

The right kidney weighed one hundred and forty-two grams, and its capsule was free. The pyramids were distorted; the substance of the kidney was soft and hyperplastic. The left kidney weighed one hundred and twenty-seven grams, and its physical characteristics were the same as those of the right.

The uterus was enlarged and contained numerous fibroid growths, both extra- and intra-mural, and they varied in consistence from ordinary fibrous material to calcareous formation. The uterus and adnexa weighed one hundred and fifty-six grams. There was a small hæmatoma on the surface of the left ovary, but the right presented the ordinary appearance of senility. There was no pelvic adhesion.

The bladder was small, partially relaxed, and contained a small quantity of urine.

Microscopical examination of the brain, sections stained by the Golgi method, shows the dendrons to be tortuous in a majority of instances and the seat of moniliform enlargement, but not interrupted; the dendrites show the same condition, and the gemmules have disappeared. The bodies of the cells are partially

mentence of the degenerative process is well shown in a fine horizontal dendrite.

Fig. 2 shows a neuron, the apex of whose dendron has been lost through degeneration, and some of the

FIG. 2.—Seams of Liquefaction in Corpus of a Pyramidal Cell. $\times 200$. Photomicrograph by Dr. W. C. Borden, U. S. Army.

FIG. 1.—Section of Cerebral Cortex Showing Moniliform Degeneration of Dendra. $\times 250$. Photomicrograph by Dr. W. C. Borden, U. S. Army

disintegrated and vacuolated; especially is this the case with the pyramidal cells.

Sections stained by Nissl's method show a granular degeneration of many cells, and the nuclei have a tendency to color as well as the bodies of the cells, the nucleoli being pale, enlarged, and irregular in outline, or else entirely absent. A thrombotic condition of the arteries and veins of the cortex existed throughout, the blood-vessels appearing straightened and stiffened, and obliterating the lymph sacs in some places. There was no effusion in the lymph sacs. Many nerve cells were vacuolated, the cell degeneration in some cases consisting in a sort of sacculation of the nucleus, which projected in the form of half a dozen expansions, reaching nearly as far as the outer border of the cells.

Cultures from the brain cortex and from the cerebrospinal fluid gave Fränkel's pneumococcus.

Description of Microscopic Sections.—In Fig. 1 two neurodendra are shown on slightly different levels, so that the second is less well defined than the first; they show several large moniliform swellings. Not only the gemmule but half of the dendrites have disappeared; and on the right of the picture the com-

moniliform swellings of two of the dendrites is all that is left of them; but the afferent nerve fibres in the vicinity are left almost intact. The corpus of the cell shows two seams of liquefaction running almost vertically through it, while the neuraxon is not markedly affected.

In Fig. 3 the cell in Fig. 2 is reproduced on a slightly different plane, and the tangential afferent fibres near the top show head-like swellings which exist in health, though possibly somewhat enlarged in this case. On the left of the picture is shown a cell corpus in which the degeneration took the form of

FIG. 3.—Granular Degeneration of Corpus of a Pyramidal Cell on the Left, and Part of Fig. 2 on the Right. $\times 200$. Photomicrograph by Dr. W. C. Borden, U. S. Army

granular masses, only about one-third of this cell taking the impregnation normally. The dendron is denuded and there is slight moniliform degeneration of the processes at the base.

A faint but distinct view of the blood-vessels and of the glia cells is given in the original photographs, which were taken by Dr. W. C. Borden, U. S. A., from gold-stained sections (Golgi-Obregia) made in the St. Peter State Hospital pathological laboratory, from the cortex of the motor area on the left side.

DISEASES OF THE TRACHEA, BRONCHI, AND LUNGS, TREATED BY INTRATRACHEAL INJECTION.

By JOSHUA LINDLEY BARTON, M.D.,

NEW YORK,

ATTENDING PHYSICIAN TO THE DEPARTMENT OF OUT-DOOR POOR, BELLEVUE HOSPITAL; PHYSICIAN TO THE LUNG DEPARTMENT OF THE NEW YORK THROAT AND NOSE HOSPITAL.

STANDARD authorities upon diseases of the nose and throat make almost no allusion to the trachea, nor to the frequency with which cough and changes in the voice, for which the laryngologist is so often consulted, originate in this organ.

The consensus of opinion seems to be that diseases of the trachea should be classed with diseases of the chest.

A study of the subject has, however, convinced me that the diseases of the trachea present so many analogies and are so closely related to those of the larynx, that the separation of tracheal from laryngeal diseases is not altogether practicable.

On the other hand, the intimate connection between the trachea and bronchi and the pulmonary parenchyma renders it difficult to separate them wholly from diseases of the lungs. We are therefore forced to the conclusion that the laryngologist should also be a pneumologist and be an expert in diseases of the whole respiratory tract.

The special physiology of the trachea was elaborately studied by Mr. Nicaise in 1889, and a *résumé* of his work presented to the Paris Academy of Sciences. He showed that "in the state of normal calm respiration the trachea remains slightly contracted and does not change its volume appreciably. The posterior extremities of the annular cartilages are almost in contact and the membranous portion lies in a linear fold. During strong respiration, in crying, groaning, singing, etc., the trachea is dilated and lengthened while the larynx rises; in inspiration the trachea shortens and contracts again."

There occurs therefore a rhythmical change in the calibre of this tube, the exact degree of which can be measured. The dilatation is in proportion to the force of the expiration, and is greatest in the upper part. The dilated trachea acts as an elastic tube, compressing the contained air. By virtue of this property it serves an important use in the production of the voice, modifications of which may be caused by pathological changes in this organ.

The tracheal nerves are derived from the great sympathetic and from the pneumogastric and its recurrent branches, filaments of which extend into the mucous membrane of both the trachea and the bronchi.

Experimental, physiological investigation seems to have definitely decided that cough may be produced by direct irritation of either of these nerves or of their branches, or of the mucus membrane supplied by them. Clinical experience proves that the converse is also true, viz.: That cough may be alleviated if not entirely prevented by appropriate medication applied directly to the irritated mucous surface.

To the late Dr. Horace Green, of this city, must be awarded the honor of being the first to advocate intratracheal medication.

In 1838 he succeeded in passing a small sponge saturated with a solution of nitrate of silver through the glottis into the trachea. In 1840 he brought the subject before the New York Medical and Surgical Society, and reported fifteen cases of severe laryngeal and bronchial diseases which had been cured by this means. In October, 1854, he adopted the plan of passing an elastic tube through the larynx into the bronchi in a patient suffering with phthisis, and of injecting from one and a half to two drachms of strong nitrate-of-silver solution into the lungs. "This process he repeated seven times in fifteen days, with the result that the patient's cough and expectoration were greatly diminished, she grew stronger, breathed with more freedom, and increased in weight."

In February, 1855, he read a paper on the subject before the New York Academy of Medicine. His statements were received with incredulity and by many he was branded a charlatan and his practice a humbug. The paper was referred to a special committee of seven, who were to investigate Dr. Green's method and report their conclusions to the academy. This committee took six months to consider the subject and then sent in a majority report unfavorable to Dr. Green and a minority report fully sustaining him. Through it all Dr. Green never lost his faith, but reiterated his belief that this practice was but the initiatory step to a plan of treatment that would ultimately result in positive good to suffering humanity. From October, 1854, to February, 1856, he had treated one hundred and six cases. Of these seventy-one were classed as cases of tuberculosis. Of these tuberculosis cases thirty-two were considered as cases of advanced tuberculosis and thirty-nine as cases of early tuberculosis. Of the cases of advanced tuberculosis twenty-five were more or less improved, their lives being apparently prolonged by this means of medication. Seven only were not improved by the injections.

Of the thirty-nine cases of incipient tuberculosis twelve had apparently recovered at the time the report was written and five more were nearly well. Of the remaining twenty-two cases seventeen were greatly improved, three were moderately benefited, and three failed to receive any benefit whatever. Of the twenty-eight cases of bronchitis sixteen were cured and all of the others greatly benefited. In six cases of asthma treated by this means, in all except one the disease was entirely removed by the use of intrabronchial injection.

December 22, 1859, four years after the reading of his first paper upon this subject before the Academy of Medicine, Dr. Green read a paper "On the Difficulties and Advantages of Catheterism of the Air Passages" before the Medico-Chirurgical College, in which he pointed out some of the errors of his early practice and advised that for intrabronchial injection milder solutions should be used. He further adds: "Such has been the amount of success which has continued to attend this plan of treatment, that I am now ready to affirm, after an experience of many years in a field of observation unusually large, that, if I were required to relinquish all other known therapeutic measures or topical medication, in the treatment of thoracic diseases, I should choose the latter with hygienic means alone, in preference to the entire class of remedies ordinarily employed in the treatment of these diseases. During the three or four years since my report of one hundred and six cases, I have treated large numbers of patients afflicted with chronic laryngeal and bronchial diseases, with asthma, and with tuberculosis, and the success which continues to attend this practice has served to increase greatly my confidence in this measure as a therapeutic agent."

In addition to the testimony of Dr. Green, eminent

medical authorities¹ in France, Germany, and Great Britain agreed that as a therapeutic means intrabronchial injection merited more serious attention.

Dr. Green asserted that the patient should be properly prepared before intratracheal or intrabronchial medication should be attempted, and with this end in view he painted the pharynx, epiglottis, and larynx with a strong solution of nitrate of silver for several successive days or weeks, in order to numb the sensibility of the mucous membrane before attempting to introduce either the sponge or the tube.

There is little wonder that this method seemed too heroic, or that many eminent physicians looked upon it with disfavor, or that with the introduction of powerful spray apparatus it fell into disuse. It must be conceded that the use of the spray, the nebulizer, and the pulmonary inspirator, is productive under certain conditions of good results, but it is impossible by their use to project into either the trachea, bronchi, or lungs a sufficient quantity of the medication to materially alleviate the cough, to soften the secretions, or to protect the irritated mucous membrane.

A revival of intratracheal and of intrabronchial injection in a modified form is therefore exceedingly desirable, and this has been rendered possible by laryngoscopy and the discovery of cocaine, facilitating as they do the easy insertion into the trachea of the endolaryngeal tube, while the great advances made in materia medica and therapeutics during the last forty years have placed in our hands a large number of remedies well suited to the purpose.

Recent scientific research has fully confirmed the observations of Dr. Green, and proved beyond a doubt that substances injected into the trachea are not only borne but are rapidly absorbed.

In the *MEDICAL RECORD* of December 1, 1883, it is stated: "At a recent session of the French Association for the Advancement of Sciences held in Rouen, Dr. Bergeron presented a memoir on the subject of the injection of medicated substances into the trachea, in which he asserted that the injection of medicated liquids into the respiratory passages below the larynx was very well borne by cows, horses, and dogs."²

In the *MEDICAL RECORD* of October 10, 1885, it is stated that "some experiments made by Dr. Pernice show that liquids injected to the trachea run down the posterior surface and are thence evenly distributed through all the bronchial twigs. They are absorbed by the pulmonary veins or by the lymphatic vessels and thus exert both a local and a systemic action. When the animal was placed in the supine position, with the head elevated a little, no cough was excited by the operation."

Dr. Pernice used in his experiments distilled water, milk, and defibrinated blood. Absorption was complete and no respiratory trouble of any sort resulted. He also used solutions of tannin, borax, benzoate of sodium, quinine, morphine, nux vomica, and lime water.³

Kirke's "Physiology," page 380, ed. 1892, states: "It is a remarkable fact that not only is the epithelium of the pulmonary mucous membrane able to allow the passage through it of gases and volatile substances, but that under certain conditions fluids such as water may also be absorbed, and besides this the presence of carbon particles in the bronchial glands and alveoli in connection with the lungs must point to the pulmonary epithelium as the only possible channel of absorption."

Again quoting from the *MEDICAL RECORD* of Feb-

ruary 8, 1896, Dr. C. G. Coakley, in a series of experiments conducted at the Loomis Laboratory, made a solution of India ink, filtered it, and then injected ten cubic centimetres of the filtered solution into the trachea of rabbits, and the animals were killed in from fifteen minutes to two hours. It was found in every case (whether fifteen minutes or two hours had elapsed) that not a trace of the pigment could be found in the trachea, bronchi, or alveoli, but all had been absorbed. Except where a few lymph cells had ruptured there was no free pigment in the lymph channels, but was all contained within the lymph cells or phagocytes, which were scattered through the lymph channels of the lung, underneath the pleura, and in bronchial glands.

Dr. Joseph Muir, of this city, who has perhaps had the largest experience in recent years of any American physician in this method of treatment, in a paper read before the Medico-Surgical Society, January 6, 1896, and since published in pamphlet form, claims that "A process analogous to that of pneumo-koniosis is induced. Substances are taken up by the lymphatics, transported downward and inward to be deposited in tissues more or less remote, even sometimes as far as the thicker connective tissues of the lungs."

It follows therefore that if absorption of injected liquids by the lymphatics of the tracheal, bronchial, and pulmonary mucous membrane has been fully demonstrated by competent observers who have also added their testimony to the ease with which such injections are borne, we are justified in resorting to intratracheal and intrabronchial medication both as a palliative and as a curative measure.

The technique is simple. A syringe with an endolaryngeal tube, devised by Dr. Muir and manufactured by Ermold, holding four drachms answers the purpose perfectly. The larynx having been sprayed with a two-per-cent. solution of cocaine, the patient is instructed to grasp the tongue with the right hand, to draw it forward, at the same time throwing back the head and opening the mouth as widely as possible. The operator, with the laryngeal mirror in one hand and the syringe in the other, then proceeds as though he were about to make a laryngeal application. As soon as the tube enters the cavity of the larynx the epiglottis is pulled slightly forward, the patient is instructed to breathe, the cords separate, the tube enters the trachea, and the syringe is emptied of its contents. By pointing the instrument to either side the bulk of the medication may be made to enter either the left or the right bronchus.

If care is taken when inserting the tube to avoid touching the glosso-epiglottic or the aryteno-epiglottic folds or the inter-arytenoid space, each one of which seems to act as a cough centre, the irritation caused by this procedure will be found to be surprisingly slight. It is in fact so non-irritating that after a little preliminary training the cocaine spray may be discontinued.

The remedies employed should be soothing and the vehicle non-irritating. For this purpose olive oil, cod-liver oil, glycerin, mucilage, or any one of the petroleum oils may be used. Of the latter the one sold under the name of benzoinol is probably the best. It is tasteless, non-irritating, and is said to contain an ounce of benzoin to the pint of oil. Solutions containing benzoinol, euophen, and menthol, or benzoinol, guaiacol, and menthol, have proved very efficacious in my hands.

From one per cent. to two and one-half per cent. of euophen and from one per cent. to fifteen per cent. of menthol, or two per cent. of guaiacol in place of the euophen, will be found to be quite strong enough.

The strength may, however, be increased or diminished to suit each individual case, or other remedies,

³ Il Movimento, No. 12, 1885.

such as ichthyol, may be substituted. From one-half a drachm to one drachm may be injected at each insertion of the tube. And this may be repeated at one sitting until from two to four drachms have been used.

This method of medication has many advantages, viz.:

1. The remedy is applied directly to the irritated mucous surface.

2. It immediately alleviates the most distressing symptoms, adding at once to the comfort of the patient.

3. In a certain number of cases the antiseptic effect of the medicine is very pronounced, as shown by the longer interval between the febrile attacks and by their lessened intensity when they do occur.

4. The tracheal and bronchial mucous membrane rapidly absorbs the medication, so that we may expect a general as well as a local effect.

5. We avoid disturbing the patient's stomach with nauseating doses and the shattering of his nervous system with opiates.

6. This method of alleviating the most distressing and annoying symptoms does not interfere in the slightest degree with any other line of general treatment which may be deemed advisable.

7. In cases characterized by an atrophic condition of the tracheal mucous membrane or of pulmonary disease with cavitation leading to retention and decomposition of the secretions, intrabronchial injection will remove the disgusting fetor of the breath consequent upon this condition.

I have treated during the past winter twenty-five cases by intratracheal injection, including cases of severe laryngo-tracheitis, bronchitis, and tuberculosis, and one case of asthma.

The cases of laryngo-tracheitis and of bronchitis were rapidly restored to health; the case of asthma was greatly improved, while every case of tuberculosis has been markedly benefited.

Report of Ten Cases.—Fred. W——, aged thirty-five, cabinet-maker. Ill since November, 1895. Began to cough about December 15, 1895. Had lost twenty-five pounds in weight. He presented himself at my clinic at Bellevue Hospital, Out-door Poor Department, January 31, 1896. Marked anæmia of larynx, with great irritability of pharynx. Severe cough. Expectoration profuse. Examination of chest showed well-marked pulmonary disease. Gave intratracheal injection of benzoinol, euophen, and menthol. The alleviation of the cough was almost immediate. The injections were repeated upon February 7th, 10th, 14th, and 19th, when the patient reported that his most distressing symptoms had been relieved, and that he could eat and sleep and enjoy himself. And like many another clinical patient he ceased his visits.

Charles J. M——, aged forty-two, waiter. General health good. Laryngo-tracheitis with bronchitis lasting four weeks. Had been under treatment for the cough, which was severe, for nearly one month with no relief. January 15, 1896, I began to treat him by intratracheal injection, using benzoinol, euophen, and one-half per cent., and menthol, seven and one-half per cent. These were repeated five times in seven days, when the patient reported that his cough was entirely well.

George M——, baker, aged twenty-five. General health good. Had had attacks of asthma every winter. I saw this patient first February 19th. He was suffering from an asthmatic attack of very great severity. I gave him an intratracheal injection of benzoinol, euophen, and menthol. The relief afforded was marked. Within ten minutes he could breathe freely and felt perfectly comfortable. This patient was under treatment for about ten days and was greatly improved.

February 16th, Mrs. R——, aged forty-five. Had la grippe about one year ago. Had not been well since. She stated that she had night sweats, had lost flesh, coughed a great deal, and expectorated freely. An examination of the sputum showed the presence of tubercle bacilli. This patient has been treated by intratracheal injections, receiving them three times a week; her appetite has improved, the night sweats have ceased, the severity of the cough has been relieved, and she has gained ten pounds in weight. She is still under treatment.

George S——, policeman, aged forty-five. Laryngo-tracheitis with cough lasting four months. During all of this time he was treated by sprays, inhalers, and expectorant mixtures, with slight relief. February 15th I began to treat him by intratracheal injection. He began to improve at once; the injections were repeated from three to four times a week for about three weeks, with the result that the patient's health is fully restored.

Thomas K——, aged thirty-seven, janitor. Had la grippe one year ago. Severe cough since July, 1895. Had lost flesh. Expectoration profuse and tinged with blood. Evening temperature 102° F., with copious perspiration at night. Physical examination revealed extensive pulmonary disease upon the right side, while the microscope showed the presence of tubercle bacilli. Notwithstanding the fact that this patient had been constantly under treatment for months, and had been three weeks in the hospital, his cough was without exception of the most distressing and persistent character. February 22d I began to treat him by intratracheal injection: benzoinol, euophen, and menthol were used. The relief was immediate. The cough became soft and less persistent, expectoration easy. The fetor of the breath disappeared. The appetite improved. The night sweats have ceased, and the temperature in the evening is normal. This patient is still under treatment.

February 21st, Miss Mary W——, aged twenty-one, domestic. Atrophic rhinitis, with severe cough and huskiness of the voice, lasting for weeks and resisting the ordinary methods of treatment. Diagnosis, laryngo-tracheitis. February 21st I treated her by intratracheal injection. The relief was immediate, the good effect of the first injection lasting for two days. Three injections removed the symptoms of which this patient complained.

Mrs. W——, aged fifty-five. Subacute tracheitis with feeling of tightness across the upper part of chest. Voice hoarse and cough persistent. March 14th she received an intratracheal injection. The relief in this case was simply magical. Within ten minutes the hoarseness in her voice had disappeared. The sense of constriction across the upper part of chest had vanished, and the desire to cough was gone. The injections were continued for one week and then three times a week until the present time. Result, the patient is practically well.

John W——, aged twenty-eight. Has coughed for one year. Has night sweats. Recently he has lost in weight, at the rate of two pounds weekly. Cough very persistent and severe. February 17th he received an intratracheal injection and that night for the first time in months he slept well. There has been a rapid alleviation of all the most distressing symptoms in this case. The patient is still under treatment.

John S——, aged thirty-five, laborer. Bronchitis with occasional attacks of asthma. Had taken expectorant mixtures and cod-liver oil without benefit. March 1st he received his first intratracheal injection. This treatment was continued several times a week for three weeks, when the patient reported that he felt like a new man, all of the symptoms of which he complained having disappeared.

THE KNIFE FOR COCCYODYNIA A FAILURE.

BY LUDWIG BREMER, M.D.,

ST. LOUIS, MO.

As a deterrent example of meddlesome and noxious surgery, I will briefly cite this case: A woman about forty years of age slips on the pavement and lands with no very great violence on the buttocks. Barring a nervous and excitable temperament, she has up to the time of the accident enjoyed uninterrupted good health, has healthy children, and is of a cheerful disposition. Immediately following the accident a painful sensation manifests itself at the end of the spine, a coccygodynia has suddenly developed, which persists to the present day, over three years after the accident.

These three years have been a continued martyrdom with the following phases, which may be said to be typical of cases of this kind. In due course of time, after having exhausted all kinds of local applications, the pain becoming more severe as time wears on, she consults a surgeon of repute, a professor in one of the leading colleges of the country, who tells her that the coccyx must be removed and that such an operation, which is a comparatively simple one, cures the affection nine times out of ten. The operation is performed by a local surgeon, with the result that the pain becomes more intense than ever. In addition to a sore and a sensitive coccyx there now exists an irritable and painful scar. A second operation is advised: for it is claimed the first one has not been thorough enough. Before submitting to this she resolves to try electricity, which is recommended to her as being very effectual in relieving such conditions. The faradic current of medium strength is used, one electrode being placed in the rectum, the other over the sacrum. The result of this single application is a cramping of the rectum, which is added to the already existing pain and which has not left her up to the present day. Stretching of the sphincter ani, which is now resorted to by her physician, instead of affording relief, increases the painful contractions. She becomes unfit for the discharge of her domestic and social duties until her physician prescribes morphine to be given by the rectum. From this day on she knows that, to lead an existence which can at least be tolerated, she has to resort to morphine. Half a grain suffices to render her condition tolerable. It enables her to follow without serious inconvenience her customary pursuits. But her family look upon her as a morphine fiend and she herself smarts under the stigma and self-reproach on account of the habit which, she is told, is worse than the liquor addiction. This constitutes another factor in rendering her existence miserable.

Consequently at the solicitations of her family and friends she makes up her mind to enter a sanatorium to cure her of the morphine habit. For three months the withdrawal of the drug is tried systematically. She becomes sleepless, loses weight and strength to such an alarming degree that the attempt of weaning her from the drug has to be abandoned. Neither massage, hydrotherapy, electricity, nor the other devices in vogue at sanatoriums have had the slightest effect upon her. It takes another three months to regain the strength she had on entering the institution. Since then she has tried all sorts of doctors and methods, has travelled extensively, sojourning at a variety of health resorts and watering-places, all to no purpose. In order to relieve an otherwise unbearable existence she has to resort to the morphine in doses of from one-quarter to one-half a grain a day.

On presenting herself to me for examination and consultation, this patient has the appearance of a

healthy, well-preserved matron, whose looks do not betray the slightest trace of the Iliad of woes which she relates in a graphic manner. Knowing by experience with other cases that coccygodynia is almost always one of the symptoms of hysteria, sometimes apparently monosymptomatic, all the other manifestations of the disease being overshadowed or rendered dormant or insignificant by the overtowering dominance of one—the excruciating pain, I make the preliminary diagnosis of hysteria.

Of course I look for hysterical stigmata, but there are none: above all, there is an absence of anæsthesia of any kind anywhere, nor is there the slightest indication of a history pointing to hysterical attacks. This woman has been exceptionally healthy all her life. But on close examination I find that travelling and change of scenery lessen the pain, that at times she is slightly aphasic, that there is a tendency to a pulling back of the head, and that often she has "a lump in the throat." I add to this that she is of a gay temperament, and that in spite of the overwhelming pain she has at all times, but which is particularly aggravating in the sitting posture, she does not present the aspect of a sufferer after having sat in my office for a number of hours, and I come to the conclusion that in the present case the coccygodynia is of an hysterical nature.

The text-books on medicine, and those on neurology in particular, describe the affection spoken of as being neuralgic or rheumatic in character. Probably there exist such cases, although among the dozen that during the last twenty-five years have come under my observation not a single one was of such nature. They were all symptomatic of hysteria, some of them apparently but not in reality monosymptomatic. For it is a striking fact that most women thus afflicted positively declare that there is nothing else the matter with them, though closer inquiry brings out the fact that a number of minor complaints exist or have existed, which, however, are ignored or have been forgotten. Hysteria is noted for the tendency to oblivion of ills that have passed.

In all cases of coccygodynia that I have seen, a history could be elicited, if not of hysteria proper or some allied neurosis in the ascendants, at all events of the existence of the hysterical temperament. In all of them an immediate or provoking cause, a provoking agent (*agent provocateur* of Charcot-Guignon) could be demonstrated. A trauma, severe and prolonged emotional and intellectual strain, infectious diseases, convalescence, parturition and lactation, chronic intoxication (alcoholism, saturnism, etc.) can generally be shown to have existed before or at the time of the cropping out of the trouble. The case briefly reported above is one of traumatic (monosymptomatic) hysteria. The several therapeutic procedures (insignificant in the healthy) acted like so many distinct shocks and provoking agents. The administration of the anæsthetic (in some predisposed individuals this alone suffices to bring about hysteria, transient or lasting) in conjunction with the wound, and later on the irritation set up by the introduction of the electrode into the rectum, sufficed to aggravate a condition which, if left to itself, would probably have remained within the bounds of toleration.

But it is just at this point where a fatal idiosyncrasy of hysterical patients plays such a baleful part. If it is true that there is such a thing as the *furor operandi* among surgeons, it is equally true that there is a class of women who actually itch for an operation, the bloodier the better. This is one phase of hysteria. The desperate monotony of an excessively painful and annoying affection engenders a craving for something phenomenal. They look upon their suffering as unique in atrociousness and unexampled in

medicine, and nothing short of an extraordinary measure will, in their opinion, be of any avail. As a rule, nothing short of an operation will satisfy them, and generally they do not meet with any difficulty in finding a surgeon who is willing to operate. It is needless to add that he is convinced of the appropriateness of surgical interference in cases of this kind, only he is mistaken as to indication and disappointed as to outcome.

The following case will furnish additional proof of this proposition and help to elucidate the subject more fully.

A woman of about thirty-five, whose mother is still living and is suffering from hysterical hemiplegia, and whose father died of apoplexy at the age of thirty-five, presents herself with this history: Up to about two years ago she has been healthy. She always has been of a hopeful, mercurial disposition. For a number of years she has nursed an invalid husband who died with consumption. After his death she has taught school and worked very hard. While thus engaged in work with which she never has been familiar, a pain constantly increasing in severity gradually develops at the sacrum and in the coccygeal region. In due course of time she is operated upon. The coccyx, which the surgeon says points inward to an unusual degree, is excised. Then the trouble gets worse. To the deep-seated pain a hypersensitive cicatrix is added. A specialist for rectal diseases now examines her to see whether any rectal trouble exists that may account for the pain. Nothing is found; but from the time of the examination an additional painful spastic condition of the rectum develops. There is also a drawing and gnawing sensation in the skin over the hips. She is in a deplorable condition, not only physically but mentally. The exacerbation of the pain affects in an indescribable manner her mind, so she claims.

In this case there are also a tendency to retraction of the head and an alleged impairment of memory, which on closer examination proves to be partial aphasia. She craves sympathy and thinks nobody understands her case or has any idea of her sufferings. With any and everybody she discusses her strange malady, though she is a woman of tact and refinement. There are no positive hysterical stigmata; only one side of the body, the left, gets numb at times and is weaker than the other side.

In this case there is well-established heredity, which by grief, anxiety, and hard work is developed into hysterical coccygodynia of a grave form.

The symptoms on which the diagnosis hysteria is made in these cases may seem to some to be insufficient, but they are fully conclusive to the neurologist, when properly grouped and interpreted in the light of Charcot's teachings. What Charcot and his school have not mentioned in their classic delineations of the syndromes of hysteria are the spastic tendency of the retractors of the head and a trace more or less noticeable of aphasia. I consider them as stigmata of a subtle character, the anæsthesias being of a coarser kind. They are very common in hysterical females and sometimes the only obvious ones in a chaos of indistinct and undefinable malaise.

To use a knife on such patients is a grave mistake. To cut off a painful coccyx is as irrational as the removal of the ovaries in hysterical ovarialgia. The time will come when another generation of medical men will look upon such operations as one of the most remarkable aberrations of the science of medicine. The trouble is in the brain, but not at the periphery, neither bone nor skin. It is projected from the centre to the periphery, as an irritation of the ulnar nerve at the "crazy bone" is to the little and fourth fingers.

Some cases of hysterical coccygodynia get well by the most divergent and heterogeneous remedies, such as hydropathy, faith cure, hypnotism, etc. Others never recover under any treatment. In such cases there is only one course left to render life tolerable, that is the use of opium. The substitution of a lesser evil for a greater one is the last refuge for the unfortunate sufferer. Many will, through a physician's prescription or by their own doing, resort to this drug. If they do not take more than half a grain a day, preferably by the rectum, they may live in comparative comfort. But generally hysteric people have a morbid dread of opiates. The fear of becoming a morphine fiend and the unpleasant untoward effects of morphine in customary doses, say one-quarter of a grain, has a deterring effect which on the whole is very wholesome. But there are cases in which moderate morphinism is preferable to a life of constant agony, not only to the patient herself but also to her family.

That even severe cases of coccygodynia may get well I have witnessed in the instance of a woman of thirty-seven. The operation had been decided upon, when her husband, who was well-to-do, failed in business. The operation was postponed and never performed. The necessity of hard work brought about a cure. The change from an idle, fashionable existence to the cares and responsibilities of running a restaurant effected a gradual but permanent cure. She herself considers her husband's failure a wind-fall. I know of another case of medium severity which was cured by the bicycle.

Excision of the coccyx is also practised to some extent on hypochondriacs. Here the diagnosis generally reads: "The coccyx points strongly inward, is partially detached, and probably necrosed." What a revelation in pathology!

I do not mean to say that never and under no circumstances has the removal of the coccyx been successful in curing the pain. Perhaps there are cases in which the operation has been beneficial. Personally I do not know of any. Even in cases of success the question is legitimate: Would not other and simpler means have been equally effective? Generally speaking, the results of coccygodectomy are as hopeless as neurectomy in facial neuralgia.

Will there be any fewer operations performed for hysterical coccygodynia on the strength of the foregoing remarks? I do not believe it. Like osteopathy and faith cure, the knife will continue to have its sway in the treatment of hysterical ailments. An age that has given rise to that crowning glory of surgical fakes, orificial surgery, proudly termed by its advocates the American operation, will continue to hunt at the periphery for that which lies in the centre. But a protest is always in order. Besides, I know that conservative surgeons repudiate the reckless and uncalled-for use of the knife.

In spite of this, the indiscriminate extirpation of wombs and ovaries, the slitting and enlarging of orifices of the male urethra, the excision of imaginary strictures, the clipping of the eye muscles, the cutting out of pockets of the rectum, circumcision, and the removal of the coccyx will go on with unabated vigor—all of which is the outcome of an exaggeration and misinterpretation of the import and meaning of the law of the reflexes. In the name of the reflexes a multitude of surgical misdemeanors are constantly committed.

Tuberculous Glands in the neck can be removed without visible scar through an incision within the hair line extending from behind the ear downward and inward. The glands are pressed toward this opening and caught with a hook or long narrow forceps and enucleated.—DOLLINGER.

A CONTRIBUTION TO THE STUDY OF ACUTE DELIRIUM, WITH ESPECIAL REFERENCE TO ITS BACTERIOLOGY—REPORT OF A CASE.

By WARREN L. BABCOCK, M.D.,

OGDENSBURG, N. Y.,

ASSISTANT PHYSICIAN, ST. LAWRENCE STATE HOSPITAL.

ACUTE delirium, according to our present conception of the disorder, is a peri-encephalitis which has a varied etiology. A review of the articles on the subject in the latest editions of our standard text-books reveals the fact that a total of forty-two alleged exciting and predisposing causes are responsible for this disease. It is a matter of much significance that such a diverse etiology should be ascribed to a condition which usually runs a definite, uniform course, ending in death in about three weeks. To the critical observer this contradiction of statements signifies that our knowledge of the exact nature of acute delirium is very meagre. Not only is the etiology an unknown quality, but its differentiation from allied conditions, such as hyperacute mania, toxic delirium, meningitis, and the delirium of the specific infectious fevers, resolves itself into a problem difficult of satisfactory solution. Particularly often is it confounded with hyperacute mania. This is illustrated by a study of the insane hospital reports for the past few years. Some hospitals and asylums are without a single case for months; others are never without one or more. The writer has prepared a table, showing the number of cases of acute delirium among the admissions of the last few years of about twenty insane hospitals in various parts of the country. The most surprising variation in the total number of cases of delirium to the total number of admissions is thus set forth. It ranges from thirteen cases of acute delirium out of a total of eighty-nine hundred and eighty admissions,¹ to seventy-one cases out of fifteen hundred and twenty-two admissions,² extending over a somewhat shorter period of time. As the two hospitals from which these statistics are taken are less than three hundred miles apart, climatic and other similar influences do not account for the variation. In the opinion of the writer it is wholly a matter of diagnosis, and cases of hyperacute mania were evidently included in the latter figures.

A valuable pathological contribution to the subject of acute delirium has recently been made by H. C. Wood,³ who makes the following divisions: "First, acute peri-encephalitis; second, an acute affection, primarily centred in the ganglionic cells, but without lesions that can be demonstrated by our present process." He then subdivides acute peri-encephalitis into septic and idiopathic peri-encephalitis, the former due to the action of septic organisms on the brain, the latter depending on emotional strain or functional excitement. He also states that if the observations of Rasori be correct, there must be a third peri-encephalitis, due to the presence of a special organism. Rasori found post-mortem in the cerebro-spinal fluid a small bacillus which he believed to be peculiar to the disease and which caused death to rabbits, with symptoms of acute septicæmia.

The studies of the writer in acute delirium have been confined to an effort to determine the alleged bacterial nature of the disease. Upon looking up the literature of this part of the subject, the array of evidence in favor of a germ origin for any form of the disease is very meagre, and, on first reflection, hope-

lessly conflicting. A number of germs have been found in the cerebro-spinal fluid of these cases post mortem, but no one germ can be said to be at all constant. The fluid from the case reported by Wood¹ was examined bacteriologically without finding germs of any kind. This case, however, does not offer any evidence against the bacterial nature of peri-encephalitis, as it evidently belongs to the idiopathic subdivision of the disease. The most important bacterial studies in addition to those of Rasori, mentioned above, are those of Potts and Berlet,² who cultured cerebro-spinal fluid obtained post mortem, and found the pneumococcus and the staphylococcus pyogenes aureus and albus. In another case, reported by Hunt (quoted by Wood), the bacillus pyocyaneus was obtained by culture from fluid found in the lateral ventricles. This case was found to have a nephritic abscess and the delirium apparently depended on a septic peri-encephalitis. Caruthers³ reports a similar case resulting from pelvic abscess, but unfortunately no bacteriological studies were made in this instance. Jackman⁴ reports finding the micrococcus pneumoniae crouposa in the cerebro-spinal fluid (post mortem) of a case of puerperal mania, which rapidly proved fatal. The clinical history of his case and its short duration (three weeks) leads to the belief that it was a true case of acute delirium following parturition. Of all germs found in the cerebro-spinal fluid of acute peri-encephalitis (post mortem) this germ occurs the most frequently. It has also been found in allied conditions of the membranes, such as simple and purulent meningitis, infectious cerebro-spinal meningitis, and acute cerebral abscesses following the infectious fevers. In a series of twenty-five cases of purulent meningitis examined by Netter (quoted by Sternberg) it was present in sixteen. In four of the sixteen the streptococcus pyogenes was also present. Monti⁵ and others have detected the germ in cerebro-spinal meningitis. It is, therefore, apparent that the micrococcus pneumoniae crouposa has a special predilection for the cerebro-spinal membranes, occurring in both primary and secondary affections of the meninges. Heretofore, the germ study of the cerebro-spinal fluid in acute delirium has been confined to fluid obtained post mortem. The bacterial investigations of the writer in this disease have been limited to the study of the cerebro-spinal fluid obtained during life.

The following case of acute peri-encephalitis was under my care throughout its entire course in the acute receiving-wards of the St. Lawrence State Hospital. On the twenty-ninth day lumbar puncture was performed for the relief of intracranial pressure symptoms, and the fluid was saved for clinical and bacteriological analysis. The micrococcus pneumoniae crouposa and the streptococcus pyogenes were found on examination. Death occurred on the forty-sixth day and an autopsy was fortunately procured, which is reported in full. The following clinical notes are abbreviated from the clinical records of the case, commenced on admission of patient:

CASE NO. 2,465.—Male, aged forty-six years, painter, native of New York. Admitted to St. Lawrence State Hospital, May 13, 1896. "On admission was rambling and incoherent in speech, confused, and subject to slight motor restlessness. Attention attracted with difficulty. Physical health fair." The history accompanying the patient states that "patient has no insane or neurotic relatives; uses alcohol and tobacco to excess, and had la grippe in March. First

³ Wood: "An Expiscation on Acute Delirium." American Journal of the Medical Sciences, vol. cix., 9, 361.

mental symptoms noted May 3d, when he became restless and talkative. During the past ten days he has slept scarcely any and his appetite has been poor. At times recently he has been so disturbed that it took four men to control him."

Examination twelve hours after admission: "Patient talks almost continuously in an incoherent, rambling jargon. Impossible to attract his attention or get him to answer questions. Hands and head in constant motion, as if gesticulating or emphasizing his remarks. Eyes injected, pupils contracted and do not react to light. Temperature, 99.6° F.; pulse, 80, high tension; patellar reflexes lost. Bowels sluggish, tongue dry and slightly coated. Urine limpid and pale, specific gravity 1.012, urea diminished, amorphous urates, no albumin or sugar, chlorides increased. Too disturbed to permit satisfactory examination of heart and lungs." Sulphonal, twenty grains, in hot milk, was given and patient slept seven hours. Delirium returned on awakening, but temperature fell to normal.

On the day following admission (twelfth day of delirium): "Above symptoms continue: temperature normal."

Fourteenth day: "Patient continues delirious and disturbed. Confusion of ideas great; special senses do not respond to any kind of objective stimuli; sleep obtained by means of sulphonal and bowels kept soluble with ox-gall enemata. Pulse, 84, high tension; temperature normal. Urine unchanged; takes nourishment readily; general condition comfortable."

Seventeenth day: "Delirium and motor restlessness continues unabated. Temperature, 99.4° F.; pulse, 96, irregular and weaker. Less influenced by sulphonal. Steadily losing weight and strength."

Twentieth day: "Little change in mental symptoms, except that motor restlessness has increased. Temperature, 98.8° F.; pulse, 88, weak. Heart's apex impaction feeble. Urine contains trace of albumin. Stimulants ordered."

Twenty-second day: "Delirium increased and now entirely oblivious of surroundings. Temperature, 100.2° F.; pulse, 100, low tension. Tongue dry, parched, and heavily coated; teeth covered with sordes and febrile symptoms prominent. Sulphonal fails to produce sleep; hyoscine substituted with good results. Takes liquid nourishment with slight resistance."

Twenty-sixth day: "No change in mental symptoms. Temperature ranges from 99.4° to 101.6° F.; pulse from 102 to 118. Strength declining. Stimulants increased. Urine contains increased amount of albumin."

Twenty-ninth day: "No subsidence of delirium. By means of moderate doses of hyoscine patient sleeps seven to ten hours daily. Resistive about taking nourishment. Febrile symptoms prominent and closely resembling typhoid fever. Head slightly retracted; pupils greatly contracted, and patient stupid and dull, although he still continues talkative and incoherent. Symptoms point to increased intracranial pressure, and operation of lumbar puncture was decided upon.¹ Morphine sulphate, one-fourth grain, and hyoscine hydrobromate, one-fiftieth grain, were given hypodermically, and patient fell asleep in a few minutes. Two or three drops of a four-per-cent. solution of cocaine were injected beneath skin of lumbar region and an aspirating needle inserted into subdural space without awakening patient. Needle was inserted one-half inch to the right of first lumbar spine and directed slightly upward and inward between first and second lumbar vertebræ. Flow of fluid was immediate and evinced a high degree of cerebral press-

ure, the rate of flow averaging at start forty-four drops per minute, whereas it has been determined by previous experiments with lumbar puncture that the normal rate of flow approximates six to ten drops per minute. The fluid drained away in drops for one hour, at the end of which time seventy-three cubic centimetres of clear exudate had been collected and entire amount reserved for examination. No shock followed operation and patient slept four hours."

On the following day the patient's condition was greatly improved. "Delirium partially subsided, attention could be attracted without much effort, and restlessness materially lessened. Temperature fell to normal, pulse tension lowered, and facial expression improved."

Thirty-second day: "Mild delirium continues. Incoherence well marked but attention can be attracted. Temperature normal, and pulse fair volume."

On the following day temperature rose to 99.6° F., and condition approached that which preceded puncture. Examination of urine revealed albumin and urea increased in amount and a few pus cells.

Thirty-sixth day: "Delirium gradually assuming a low, muttering form and patient's strength rapidly failing. Albumin, pus cells, and granular casts abundant in urine. Stimulants increased to one-half ounce of spiritus frumenti every two hours."

Forty-first day: "Very weak and greatly emaciated. Delirium muttering and low, like that of typhoid. Tongue dry, cracked, and brown; mouth very foul, and teeth covered with sordes. Temperature, 100° F.; pulse, 94, weak and irregular. Resistive about taking nourishment. Albuminous salt solution injected into buttocks and hypodermics of strychnine and digitalis given every four hours. After nutrient injection patient rallied and seemed much improved for twenty-four hours, at the end of which time he relapsed. Twelve hours after relapse nutrient injection repeated without further improvement."

Forty-sixth day: "Patient died at 2 P.M., after having been in a condition of coma for thirty-six hours. Eight minutes after death lumbar puncture was again performed and sixty-six cubic centimetres of turbid fluid quickly collected."

Autopsy (sixteen hours after death).—The following notes are abstracted from the autopsy record: "Body greatly emaciated. Brain found bulging and membranes tense, but only a moderate amount of fluid drained off. Tension due to the swollen condition of the cortex. Pia and arachnoid inflamed; frontal half of membranes cloudy and opaque, presenting evidence of extension of the inflammation from the frontal to the temporo-sphenoidal and thence to the occipital lobes, the inflamed area of the latter being apparently of very recent origin. The vessels of the pia were highly injected and the pia over the cerebellum was mildly inflamed. The entire cerebrum was soft and swollen, and the cortex was infiltrated with inflammatory products, thus presenting evidence of acute encephalitis. Minute punctate hemorrhages appeared on the surface of the convolutions from which the pia was stripped. The superficial layer of the cortex tore up in flakes on removal of the pia. The temporo-sphenoidal lobes were softened and the frontal lobes were adherent to each other for a short distance anterior to the corpus callosum. The olfactory bulbs were soft and atrophic; the choroid plexus was cystic; the ventricles were greatly dilated, and their walls were softened and infiltrated with serum. The meninges of the cord and nerve sheaths of both anterior and posterior roots were inflamed throughout.

The lungs were large, white, anæmic, and emphysematous; contained much frothy mucus. The lobules contained a cloudy, semi-fluid, gelatinous exudate, smears of which were saved for microscopical exam-

¹ For full description of this operation and its use in general paralysis, locomotor ataxia, and other cerebro-spinal diseases, see State Hospitals Bulletin, July, 1896, vol. i., No. 3.

ination. An ante-mortem clot was found in the pulmonary arteries, extending into the vessels of both lungs.

The heart was soft, flabby, and dilated. The left ventricle contained a small ante-mortem clot extending into the aorta. The valves were competent throughout. The right ventricle contained a large, fibrous clot, intimately blended with the muscular columns, extending through the tricuspid orifice into the right auricle. The pericardium, aorta, and heart wall were normal in appearance.

The liver was large, congested, and studded with friable, soft areas. It resembled the liver of acute alcoholism.

The spleen was congested and friable; normal in size. Blood smears were saved for microscopical examination.

The kidneys were both highly congested. The right contained a small abscess at the upper angle.

The intestines were normal. The Gasserian, semilunar, and Meckel's ganglia, retina, cochlea, and sections from all the organs were saved for microscopical examination.

Microscopical Examination.—Smears from the lungs showed broken-down epithelial cells, shreds of lung tissue, red blood corpuscles, and much granular matter. Blood smears from the spleen, stained by Gram's method, revealed the micrococci pneumoniae in great numbers. They occurred singly and in pairs, and were not accompanied by the streptococci which were found in such abundance in the cerebro-spinal fluid from the second puncture. The red cells were granular and in various conditions of transitional change. The leucocytes were normal in contour, increased in number, and some contained within themselves one or more cocci.

Microscopical examination of sections from the inflamed areas of the cortex revealed the usual appearance of acute inflammation. Nissl's stain showed that the perivascular and lymph spaces were crowded with white blood cells in various stages of degeneration. The vessel walls were swollen and the lumen of the arteries was crowded with corpuscles. Around some of the larger arterioles the lymphatic engorgement was very great; the cells were densely crowded together and evidences of granular degeneration were very apparent. The periganglionic spaces were occupied by a serous infiltration, which in some places gave way to an enormous crowding together of lymphocytes. The cortical cells in close proximity to the blood-vessels were swollen; the nucleus was distinct and the protoplasm was vacuolated in some instances. The condition of the nerve cells varied greatly in different fields examined.

Chemical Examination.—Briefly, the chemical analysis of the cerebro-spinal fluid resulted as follows: First puncture: amount, seventy-three cubic centimetres, clear; reaction, neutral; specific gravity, 1.010; albumin, 2.25 per cent.; chlorides, 4 per cent.; urea, 0.1 per cent.; sugar, negative; traces of phosphates, sulphates, and globulin. Protogon was also tested for and found. Second puncture: amount, sixty-six cubic centimetres, cloudy and opaque; reaction, neutral; specific gravity, 1.009; albumin, 3.5 per cent.; chlorides, 4.5 per cent.; urea, 0.1 per cent.; phosphates, 0.75 per cent.; sulphates, 0.25 per cent.; sugar, negative. White and red blood corpuscles, pus corpuscles, and hæmatin crystals were also present.

The large amount of albumin present suggests an intense inflammatory condition of the membranes, which evidently steadily progressed, as the albumin increased from 2.25 per cent. in the first specimen to 3.5 per cent. in the specimen of fluid obtained immediately after death. The chlorides and other salts,

traces only of which are present in normal fluid, were found to be greatly in excess, particularly in the specimen from the last puncture.

Bacteriological Examination.—Many precautions were taken in collecting the fluid during both lumbar punctures so as to exclude all possibility of contaminating it with extraneous germs. The needle, tube, and glass receptacle were previously sterilized by steam; the fluid was kept at the body temperature by means of hot moist packing about the tube and graduate, and the latter was kept covered with sterilized gauze. As soon as twelve cubic centimetres were collected, that amount was transferred to a sterilized precipitating tube and the latter was plugged with sterilized cotton. The liquid, after standing twelve hours, was placed in a centrifugal machine and its suspended solids were precipitated. After precipitation the supernatant fluid was drained off and the flocculent precipitate was stained by Gram's method and mounted in balsam. This method of precipitation and staining, with the exception of keeping the temperature of the fluid at 100° F., was carried out after the second puncture. On examination of the slides prepared from the fluid of the first puncture, large numbers of the micrococcus pneumoniae crouposa were found, together with an occasional streptococcus pyogenes. Slides from the fluid of the second puncture revealed an increased number of both germs, particularly the streptococcus. Pus cells were numerous in each field examined from the fluid of the second puncture.

As the writer had no facilities for making cultures of the germ, an attempt was made to demonstrate its specific nature by the inoculation of rabbits. Two were inoculated from fluid of the first puncture, as follows: The aseptic precautions described above were supplemented by the use of a sterilized hypodermic needle, and the fluid was kept at a temperature of 100° F. until injected subcutaneously into buttocks of rabbit. Two cubic centimetres were injected into each rabbit. At the end of twenty-four hours both had an elevation of temperature of little more than a degree, and manifested symptoms of a mild septicaemic infection. At the end of forty-eight hours their temperature was still elevated and they were eating poorly. Twenty-four hours later they seemed to have regained their usual condition.

Three rabbits were inoculated with fluid from the second puncture in the manner described above. At the end of twenty-four hours two of them gave evidence of an intense infection, while the third gave birth to eight young, evidently premature. Of the young two died, while the mother manifested no further evidence of infection. The two remaining rabbits were greatly prostrated; their temperature ranged from 103.8° to 105.2° F. (normal rabbit temperature, 103.1° F.); they refused to eat and lost weight rapidly. At the end of forty-eight hours one appeared to be dying, but both recovered after a few days. An examination of the blood of these rabbits revealed the same germ that was found in the spinal exudate, which here occurred both singly and in pairs.

The microscopical appearance of the germ found in the spinal fluid and the blood of the inoculated rabbits exactly corresponds to that of the micrococcus pneumoniae crouposa or micrococcus Pasteuri (Sternberg). Its virulence upon the rabbits, however, appeared much less than that of germs from pneumonic sputum, as the animals usually die when inoculated with the latter. It is assumed, therefore, that the germs injected had from some cause or other become attenuated. The subject needs further investigation by reinoculation and culture experiments with the fluid obtained by puncture before the identity of the germ can be established. The above notes are only

offered as an incentive to more thorough work in suspected cases of bacterial peri-encephalitis.

The features of particular interest presented in this case are:

First, the temporary relief of the cerebral symptoms and improvement in the patient's condition following lumbar puncture.

Second, the finding of a germ, probably the micrococcus pneumoniae crouposa in the cerebro-spinal fluid obtained during life.

Third, the protraction of the delirium and the unusual length of the disease (forty-six days).

RUPTURE OF THE UTERUS.¹

By JOHN C. MACVITT, M.D.,

BROOKLYN, N. Y.

ONE of the most formidable, dangerous, and unexpected accidents to the parturient woman with which the obstetrician has to contend is rupture of the uterus. Without the slightest premonition the attendant is carried from a peaceful contemplation of a natural process to a most direful result. In the literature of the subject it is the exceptional author who outlines any premonitory symptoms, and they are so vague and difficult to appreciate that until time and experience designate more tangible evidence we will still rest in fancied security by the patient's bedside until in the presence of the disaster. The frequency of rupture of the uterus is hard to determine, owing not only to the failure of physicians to report their fatal cases, but to the fact that the greater majority of the cases are not recognized. Baudeloque in his thesis states that in his post-mortem examinations, after craniotomies, he usually found a ruptured or contused condition of the organ. Sudden deaths during labor reported as due to concealed hemorrhage, shock, embolism, heart failure, etc., are probably due to this cause. Statistics by foreign and American obstetricians of note, based upon personal and collected cases, range from one in four hundred to one in five thousand. This apparently great difference is undoubtedly due to the classification of the injury, some recognizing a tear of limited extent in the cervix or body, whereas others recognize only those whose grave symptoms indicate laceration into the peritoneal cavity. Tears in which the whole extent of the cervix is involved, according to the theory of Kaltenbach, are of a non-traumatic origin. To cure a diseased condition remove the cause, is an axiom in practice. In these cases, in most instances, the cause is unrecognizable until the harm is accomplished. Cases presenting a history of Cæsarean section, previous ruptures, or operation involving the uterus for carcinoma or fibroid neoplasm should put the attendant upon his guard to be in readiness to operate upon a moment's notice, or, better still, he should advise such a patient to seek treatment in some hospital where adequate skill and convenience for operating under proper precautions exist. A successful operation, one of the very few, in which both mother and child were saved after a rupture with protrusion of the child into the abdominal cavity, was performed by Dr. Tucker, of Bay City, Mich., he fortunately recognizing the rupture at the moment of its occurrence and performing without delay cœliotomy, his only instrument being a small penknife.

Many factors enter into the etiology of this accident. Eighty per cent. of these cases occurs in multiparæ, due to a thinning and weakening of the uterine muscular fibres in previous labors. It is asserted and disputed that a healthy uterus can rupture itself

through the force of its own muscular contractions. External violence, such as falls, blows, traumatism in which the uterine tissue is injured, oftentimes produces rupture. Freund relates a case in which labor appeared two days after the patient had fallen, striking the enlarged abdomen against a curbstone, and in which the uterus ruptured shortly after the onset of labor. Disproportion between the size of the child and the maternal soft parts, as exemplified by statistics, shows a great preponderance of male children in these cases. Hydrocephalus was an early recognized cause; also previous operation upon the womb, already referred to, laceration of the cervix, narrow pelvis and pelvis presenting abnormal bony prominences, the symphysis pubis and enlarged ileo-pectineal eminence being often at fault in this respect, and malpresentations presenting irregular surface to the contracting uterine muscles: but above all I believe the greater number of ruptures is produced by bad management and a failure to recognize imperative interference early enough. You can easily understand how the administration of ergot during the second stage of labor, so often indulged in by midwives and criminally incompetent practitioners, notwithstanding the well-known action of the drug, the untimely and unskilful use of the forceps, the condition of malpresentation after the liquor amnii has escaped, when the woman has been in labor for hours, without preparing her for the ordeal by the administration of an anæsthetic, will lead to this accident. The following two cases will serve to illustrate gross incompetency in management.

CASE I.—A poor, ill nourished Polish woman, the mother of two children, without any history of previous difficult labor, was taken with labor pains on the morning of January 6th. In the afternoon a midwife was sent for, and, according to her evidence before a coroner's jury, she found the woman suffering from pains every four or five minutes, with the os slightly dilated. Without waiting for complete dilatation she ruptured the membrane. This was about two o'clock in the afternoon. At eleven she left the woman with advice to the husband to send for a doctor. The doctor arrived at 3 A.M. The woman was in hard labor, head presenting at brim. Failing to deliver with forceps, the aid of a second physician was sought. A second application of the forceps was likewise futile. At 7 A.M. of the second day both these doctors took their departure, promising to return later. They failing to do this, a third practitioner was called in, who, not deeming the pains of the now exhausted woman strong enough, ordered regular doses of ergot and left the patient to nature and the drug. He returned at eleven o'clock that night to find the woman vomiting and in a state of collapse. He sent for a consultant, upon whose arrival the bladder was catheterized and bloody urine withdrawn. It was then decided to send for an ambulance to remove her to a hospital. The ambulance surgeon arrived at the house at about 5 A.M. the third day of the woman's labor. She then presented marked pallor of the face and lips, wrist pulse weak and rapid, with every evidence of complete exhaustion with entire absence of pains. On examination the surgeon found a prolapsed, pulseless cord, with head presenting at brim but not wedged in. Having been informed of the fruitless efforts of the four physicians who had preceded him to deliver with the forceps, he proceeded to do an internal podalic version, which he states he accomplished with comparative ease. He experienced but little difficulty in delivering the body and extremities, but the head remained fast. After vainly trying to deliver this he severed the body from the head and brought the woman to St. Mary's Hospital, where I was sent for to complete the attendance. As you can

¹ Read at the fourth annual meeting of the Association of Alumni of St. Mary's Hospital.

well imagine, the woman presented all the appearance of approaching dissolution from collapse. The abdomen was greatly distended, tense, and painful, showing the presence of general peritonitis, and in consequence of this condition nothing could be determined by abdominal palpation.

Upon the introduction of my hand into the uterine cavity I found it filled with intestines. The decapitated head I could feel between them, receding before my fingers into the peritoneal cavity. I found it somewhat difficult to gain possession of this, owing to its moist, rounded form, but finally, getting my index finger into the mouth, I gently worked it back through the widely torn rent into the uterine cavity and down to the pelvic brim. I retained my purchase and an assistant was able to grasp with a strong pair of forceps the remaining portion of the neck, which he held until I applied a pair of obstetrical forceps and delivered the head, the placenta following directly. I was desirous of doing a cœliotomy, cleaning out the abdominal cavity, and stitching the torn womb, but on consulting with the medical gentlemen present it was deemed unwise, owing to the patient's condition. I then endeavored to produce an inversion with the intention of amputating the womb, but my efforts, together with the stimulants the patient was constantly receiving, brought on contractions, which rendered my efforts of no avail. The uterus was then crowded down into the pelvis and held there by abdominal compresses and bandages. After douching out the cavity with a weak solution of carbolic acid, an iodoform drain was inserted into the rent, and the patient removed to the ward where she died five hours afterward. I will leave comment upon this case to the members of the association.

CASE II.—A strong, healthy German woman, mother of seven children, upon the appearance of labor pains sent for the doctor she had engaged to attend her. On his arrival he stated he was in a great hurry, made an examination, ruptured the membrane, applied the forceps, and delivered. One week afterward she was brought to St. Mary's Hospital. On an examination by Dr. John Byrne, the bladder, vagina, and uterus made but one cavity. Fortunately, in this case the uterine rupture did not extend into the peritoneal cavity. After waiting for proper involution, Dr. Byrne, at one sitting, made a thorough and successful restoration of the parts. A few days ago I learned from the doctor that the woman was again pregnant.

The position of the ruptures in these cases is not so much a matter of moment as their extent. Sometimes the cervical portion is torn from their body. The majority of the tears have their origin in the thin obstetrical neck and extend transversely and longitudinally. This portion of the uterus is passive during a pain, and, it being also the thinnest, you can understand how the force of the contracting fundus, pressing the fœtus against the bony brim, can destroy the integrity of the intervening wall. Rarely there may be an external rent in the walls of the uterus without injury to the peritoneum and conversely.

I believe it to be a difficult matter to detect any but a rupture of so grave a character that there can be no mistaking the objective symptoms. Some ruptures are progressive and cannot be recognized until completion of the disaster. But there can be no mistaking the following symptoms: During the acme of a pain the woman experiences a sensation of something tearing or giving away, followed by vomiting, faint, pallor, shallow respiration, coldness of the extremities, in fact all the symptoms of shock: cessation of the pains generally, but not always; for if the arch of the fundus is not destroyed contractions can continue. If the child has entered the peritoneal cavity it can be felt through the abdominal walls, and an examination per

vaginam will show a recession of the presenting parts. Palpation of the abdominal walls will not only show the presence of the child, but the uterus can be felt as a separate body as well. Hemorrhage from the vagina also often takes place. Emphysema at the level of the hypogastric region caused by air in the connective tissue is a symptom not always present. When found it indicates a fatal termination. In my reading on this subject I have not met with the mention of a single case in which a woman with a previously ruptured uterus was afterward delivered without a recurrence of the same, an item of considerable importance in the elective treatment of these patients. Preventive treatment resolves itself into a matter of individual judgment. Treatment after rupture depends entirely upon the position of the child. If the head presents apply forceps and deliver, having an assistant steady the uterus by pressure. Failing to deliver, craniotomy is advised, but morally and scientifically cœliotomy would be the better procedure, providing the child is still alive: in other than vertex presentations with a dead child embryotomy; in case of a living child podalic version may expedite delivery, but the greatest care is necessary in order not to enlarge the tear.

In a third class of cases, in which the child is partly within the peritoneal cavity, try and deliver through the vagina. But when the child is wholly within the cavity, cœliotomy is the only justifiable operation. The old treatment of passing the hand through the uterine tear and withdrawing the child will only jeopardize the woman's chance for recovery. The old-fashioned expectant plan is not to be thought of in this enlightened era. After the removal of the child and placenta through the abdominal opening, the rent in the uterus is to be sutured, the peritoneal cavity cleansed in accordance with the rules of aseptic surgery, and the wound closed. The uterus is then to be douched out with a weak solution of carbolic acid. In cases in which the child has been delivered through the natural passage and the mother afterward develops symptoms of septicemia, it would be proper to perform cœliotomy for the purpose of removing the septic material. In other than cœliotomy cases daily irrigations and drainage are requisite. It is a disputed question whether it would not be better in all cases of rupture in which the amniotic fluid and blood have entered the peritoneal cavity to remove it through abdominal section, as it is well-nigh impossible to secure proper aseptic conditions without: but statistics of reported cases up to the present time show a less mortality when drainage and irrigation have been given the preference over cœliotomy. In cases of cœliotomy, where the edges of a uterine rent are so irregular and injured that they cannot be properly brought together, amputation of the uterus is resorted to. The mortality resulting from this proceeding has been so great that drainage is preferable. The placenta should be removed manually and not expressed.

Phimosis.—Dr. Martin (*Medical News*) says this is a frequent agent in causing or aggravating diseases in children. The indirect disturbances by reflex are often puzzling and by no means infrequent: it affects digestion very seriously at times. Prolapsus ani accompanies preputial inflammation, which will also give rise to symptoms resembling those of stone in the bladder. Phimosis will aggravate the symptoms of any coexisting disease and be the cause of slow recovery in many cases. The reflex disturbances from it are of sufficiently frequent occurrence to justify a physician in making an examination of every male child for this condition.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, August 1, 1896.

THE SIN OF SUBSTITUTION.

On several occasions previously we have condemned the practice of substituting one preparation for another in the compounding of prescriptions. The evil is a well-recognized one and, we have good reasons for believing, is more prevalent than would at first sight appear. To such as take the requisite pains to examine the question the damaging testimony against the unprincipled pharmacist is overwhelmingly evident. The difficulty of finding some efficient remedy for this gross abuse has always been great, and it is with a feeling of congratulation that we notice the action of a leading manufacturing firm of this city in placing the responsibility where it rightly belongs. The firm in question, whose products have gained for themselves a well-deserved reputation for uniformity of strength and surety of action, has directly attacked the evil in the very practical manner as set forth in the following circular to physicians throughout the country:

"DEAR SIR: We beg to call your attention to the following statement of facts, which we believe will be of great interest to you as a practising physician relying upon the pharmacist for dispensing the medicines which you prescribe:

"On a recent date a prescription of a ——— physician ordering ——— was sent to ——— drug store. The bottle dispensed upon this prescription was immediately sealed in the presence of a witness and expressed to us. A copy of the prescription was asked for and obtained, which proved to be an accurate transcript of the prescription, bearing date and number corresponding to those upon the label of the bottle dispensed. Upon examination the content of said bottle was found to be a fluid differing materially from ———, so as to be obviously recognizable as a plain violation of the physician's prescription.

"Another written order for ——— was sent to Druggist ———. Upon examination this proved likewise to have been filled with a different and inferior fluid.

"Subsequently, the same day, a messenger was sent to ——— and asked verbally for four ounces of ———. He received a wrapped vial, for which he paid fifty cents. This bottle was found without label, and the messenger returned and asked to have the bottle labelled. The druggist then simply labelled it with the name of the firm's preparation. Thereupon, the messenger requested the druggist to put 'all the name

on the bottle.' The druggist told the messenger that he 'would not dare to put the firm's name on the label, although it was all the same.' The druggist finally admitted to the messenger that he was 'out of' the particular article and then returned the fifty cents.

"There is one significant fact that should also be mentioned: the price charged in these cases (as in every instance coming to our knowledge) is the same as the patient would be charged by pharmacists who dispense the genuine medicine ordered. Comment is unnecessary.

"In defence of our own rights, and in order that you may take such means as you deem best to protect yourself and your patients, we advise you of these facts. We further respectfully request that in prescribing ——— you will kindly send the prescription to pharmacists, of whom there are many, who will faithfully respect their legal and professional obligations to physicians and to the public."

The *Pharmaceutical Era*, in commenting upon this miserable business, makes the following sensible remarks:

"We fail to comprehend what a druggist is thinking of when he permits such practices behind his prescription counter. Where is the profession of pharmacy drifting to if it has gotten to that point that a physician cannot depend upon a druggist filling his prescriptions with what is ordered? We should discredit these reports if they came from a less responsible source. Such practice if continued will work untold injury to the credit and standing of the entire pharmaceutical profession. Physicians are constantly claiming that one of the principal reasons why they handle their own medicines is that they are then sure of what they are administering. Any such wholesale accusation against the integrity of druggists is as unjust as it is untrue. There are thousands of conscientious, upright, honorable pharmacists, who would no more think of substituting in a prescription than they would of trying to pass a counterfeit bill. It is unfortunate that reflection must be cast upon these honest druggists by the acts of their unscrupulous brothers, but all of this hue and cry on the part of manufacturers about substituting cannot be ignored. Where there is so much smoke there must be some fire.

"Every honest druggist owes it to himself and his profession to speak plainly on this subject. He should adopt the most strict rules for his own establishment, improve every opportunity to condemn the practice of substituting, and see that resolutions to this effect are passed by his local, State, and national associations. Each druggist should make it a point to give his physicians and his customers to understand that when a prescription comes into his establishment it is filled with exactly what it calls for. There can be no middle ground, no compromise, no question on this point. Physicians who prescribe them and the manufacturers who make the goods must have no good cause for such complaints. The honor of the drug trade demands that this stigma be removed. It is not a question of dollars and cents alone, but professional honor is at stake, and we know that every honest pharmacist will join with us in the statement that the druggist who

substitutes in his prescriptions is a disgrace to his profession."

Aside from the question of fair dealing between man and man, of ordinary justice in trade, and common honor in protecting the consumer, this outrageous practice of substitution not only tends to distrust of the one in whom every confidence should be placed, but is a direct menace to the skill of the physician and the faith he may have in well-tried drugs. Further than this, the very life of the patient may hang upon the culpable waste of time that a substitution may entail or the substitution may eventually cheat the innocent sufferer of the only chance of ultimate recovery.

Thus the physician becomes more than interested in the exposure of such nefarious practices. Every respectable pharmacist in any community owes it to himself by word and deed to frown on the culprits and to lend his efforts in exposing their fraudulent proceedings. When the latter have been discovered no pains should be spared to make the facts known, either by disciplinary action on the part of boards of pharmacy or by suits at law. The advice to patronize only such as are known to be honest is perfectly sound. In the end we must narrow ourselves to this. There is nothing to prevent every physician who wishes to claim his rights in the premises from advising his patients to patronize such pharmacists as he has good reasons for believing are above the usual temptations of fraudulent dealings. There are plenty such and these only should be encouraged. When a substitutor is discovered he should be blacklisted once and for all. His very act, being deliberate, cold-blooded, and inexcusably dishonest, places him beyond the pale of possible repentance. He is the spotted leopard who cannot live without his skin.

FRAGILITAS OSSIUM IN THE INSANE.

A FAVORITE theme for the sensational newspaper writer is the abuse of the insane by asylum attendants. It is assumed as unnecessary of demonstration that the latter are brutal by nature and still further hardened through contact with lunatics and observation of the many wiles and treacheries of these poor sufferers. The specific charges of cruelty are often based upon the occurrence of fractures or of ecchymoses during the struggles of a patient to escape from his keepers for the purpose of committing some act of violence. It is assumed as matter of course that no such accidents can occur except as the result of unjustifiable violence. But the facts are the other way, for daily observation shows that it requires but a slight traumatism to produce ecchymoses in the insane, and a pressure on the skin no greater than that associated with the force necessary to prevent the escape of the patient may result in covering him with black and blue spots. From the same cause, the lowered nutrition in the insane, the bones may become exceedingly brittle and liable to fracture, as the result of almost inappreciable factors or even spontaneously.

At the meeting of the American Medico-Psychological Association, held last year in Denver, Dr. H. C.

Eyman, of Toledo, reported a case of this nature which barely escaped being made the subject of a newspaper scandal. The case was that of a strong man, about sixty years of age, who had been admitted to the hospital suffering from delusional melancholia. He slept in a dormitory with twenty other patients. One night he became restless and wandered about the ward, finally stopping by the bed of another patient. The latter awoke suddenly and was alarmed at seeing a man so near him. He put his foot against the patient's chest and pushed him away with some violence, but not with sufficient force to throw him down. The man went back to bed, whence he arose the following morning with the other patients and dressed himself quietly. During the day he became restless and suddenly attacked the attendant, a smaller man than himself, who was obliged to use some though no undue force in subduing him. While being conducted to the disturbed ward he broke away and ran a considerable distance before being overtaken, showing at that time no evidences of soreness or illness. A few hours after being placed in the ward, however, he complained of being ill, and examination showed several fractures of the ribs. He was at once removed to the hospital, where he sank rapidly and died in a few days. At the autopsy nineteen fractures of the ribs were found, and the bones were as brittle as pipe-stems. The coroner made a thorough examination of the case and exonerated the attendants from all blame. The man's son took the body home and then consulted some physicians who were not disposed to agree with the coroner. The case was taken to the newspapers, but although it was in the very middle of the silly summer season, they did not care to make a sensation of it and so it was dropped.

This case, had it not been for the searching investigations of the coroner and his exonerating verdict, might readily have been taken up by some scandal-mongering paper, and the physicians and hospital attendants would have been subjected to infinite worry and unpleasant notoriety.

THE PARASITES OF WHOOPING-COUGH.

THE recognized contagiousness of whooping-cough at once places this disease in the category of the infectious processes; but although a considerable number of studies have been made to determine the causative organisms, it cannot be said that this end has been satisfactorily attained. Of all those that have been isolated from the sputum the greatest significance has been attached to the bacillus described in 1887 by Afanasiew, but the pathogenicity of this also has been disputed. In a recent communication upon this subject, Kurloff (*Centralblatt für Bakteriologie*, vol. xix., Nos. 14 and 15) details the results of a study of the fresh, unstained sputum in a series of cases of whooping-cough. This observer found an amœba characterized by a finely granular protoplasm and great capability of movement, which he believes to be the infecting agent of the disease. As this organism grows it attains considerable size, large bright granular

spores appearing in its body, arranging themselves in concentric layers. Upon rupture of the cell the spores escape and proceed to increase in size, until finally, and partly within the body of the patient, through rupture of the capsule young amœbæ are set free. These are provided with cilia and are capable of active movement. Other ciliated amœboid bodies were also found, but their relation to those described was not perfectly clear. No specific significance was attached to the many bacteria present in the sputum, although the importance of these with regard to the secondary phenomena and complications of the disease must be conceded.

A SPECTACLE FOR THE SILLY SEASON.

MUCH astonishment as well as indignation has been aroused in medical circles over the curious actions of our new charity commissioners. They have had a ward set apart in Bellevue Hospital, in which they are testing a secret specific for inebriety. This is being done without the counsel or supervision of the medical board. The spectacle of the executive officers of a great and historic hospital grappling with the hard problems of experimental therapeutics ought to add much to the gaiety as it does to the silliness of the season.

News of the Week.

Obituary Notes.—**SURGEON C. S. D. FESSENDEN**, United States Marine Hospital service, died at Salem, Mass., July 23d, at the age of sixty-eight years. He was appointed to the Marine Hospital service in 1861. On November 22, 1895, he was placed on waiting orders on account of physical disability.—**DR. EDWARD GUTMANN** died in this city on July 21st. He had been ill for almost a year. He was born at Halle, Germany, in 1828. He studied medicine at the University of Berlin, and came to this country to begin the practice of his profession in 1854.—**DR. JOHN H. MCGIVERN** died at Plympton, N. S., on July 21st, after an illness of several months. He was thirty-nine years old, and was born in St. John, N. B. He received his degree from the medical school of the University of New York in 1883, and at once began to practise in Harlem.—**DR. SAMUEL SWIFT**, of Yonkers, died in this city on July 29th. He had an apoplectic attack while in a theatre on Saturday evening, and was taken to Flower Hospital. He was fifty-three years old. He was a graduate of the College of Physicians and Surgeons of this city in 1872.—**DR. M. M. WEIL**, a recent graduate of the College of Physicians and Surgeons of this city, died from poisoning by carbolic acid, taken with suicidal intent on Saturday last.

A Rejected Paper.—Mr. Lawson Tait, who is polemical, not to say belligerent, gave notice to the chairman of the section on ethics of the British Medical Association that he proposed to read a paper on "The Ethics of Advertising, Illustrated by the Manners and Customs of the Editor of the *British*

Medical Journal," but received word in reply that no attack on the editor of the *British Medical Journal* would be permitted. So now Mr. Tait proposes to publish the paper elsewhere, "where Mr. Hart may have his brittle nature less sedulously and unscrupulously protected."

The American Microscopical Society will hold its nineteenth annual meeting in the new Carnegie library building, Pittsburg, Pa., Tuesday, Wednesday, Thursday, and Friday, August 18, 19, 20, and 21, 1896.

The British Medical Association at its meeting in Carlisle this week was invited by the local profession to meet in 1898 in Portsmouth.

A New Board of Health Building.—A new three-story brick building, to be used as a stable and a laboratory by the board of health of New York, is to be erected by the city on the south side of Seventeenth Street, east of Avenue C.

The Canadian Medical Association will hold its annual meeting in Montreal on August 26th, 27th, and 28th, under the presidency of Dr. James Thorburn, of Toronto.

An Alleged Case of Cholera in London.—The cable reported a week ago that a physician had found a supposed case of cholera in Walworth Road, South London, and that the officials were examining into the case. As nothing further has been cabled, it is presumable that the disease was not Asiatic cholera.

Peace in Peekskill.—For a number of years there has been trouble in the Peekskill Hospital owing to the usual differences between the lay managers and the medical staff, and all efforts to reconcile these differences and woo back the physicians who had resigned from the staff proved futile. Recently, however, the rules of the hospital were so modified that the doctors felt they could accept the invitation to return, and they have accordingly done so.

The Third French Medical Congress will be held this year at Nancy, on August 6th–12th. There will be three set discussions: "The Application of Blood Serums to the Treatment of Diseases," "Intravascular Coagulation of Blood," and "The Prognosis of Albuminuria."

The New Jersey State Dental Society held its twenty-sixth annual meeting during the past week, at Asbury Park.

A Protest against the System of Appointments to the Public Hospitals.—A committee of five physicians from the County Medical Association called on the commissioners of charities a few days ago, to file a statement protesting against the present system of appointing physicians to the staffs of the various public hospitals and institutions in the city.

A Police Census of Physicians.—The police recently took a census of physicians and surgeons in this city, at the request of the County Medical Society, in order that there may be a complete and accurate list of the members of the profession, which is to be the basis of some investigation of the standing of certain supposed illegal practitioners.

Order of Military Surgeons of New Jersey.—At the annual session of the Order of Military Surgeons of New Jersey, held in connection with the annual encampment at Sea Girt, the following officers were elected: *President*, Maj. D. L. Wallace, First Regiment; *First Vice-President*, Maj. W. J. Parker, Fourth Regiment; *Second Vice-President*, Lieut. Leslie F. Ward, First Troop; *Secretary*, Maj. D. Strock, Sixth Regiment; *Treasurer*, H. C. H. Herald, retired. A resolution was adopted petitioning the governor to have the uniform of the medical department of the United States army adopted as the uniform for the medical department of the national guard of the State of New Jersey.

The American Public Health Association will hold its twenty-fourth annual meeting at Buffalo, September 15th to 18th. The following are the subjects proposed for discussion: the pollution of water supplies; the disposal of garbage and refuse; animal diseases and animal food; the nomenclature of diseases and forms of statistics; protective inoculations in infectious diseases; national health legislation; the cause and prevention of diphtheria; causes and prevention of infant mortality; car sanitation; the prevention of the spread of yellow fever; steamship and steamboat sanitation; the transportation and disposal of the dead; the use of alcoholic drinks from a sanitary standpoint; the centennial of vaccination; the relation of forestry to public health; transportation of diseased tissues by mail; river conservancy boards of supervision. This is a rather wide range of subjects to be disposed of in four days.

"Climate and Health," a publication of the weather bureau of the United States department of agriculture, has been discontinued, owing to the failure of Congress to make the necessary appropriations.

The Convalescent Dinner Society is a London association which undertakes the duty of granting in well-authenticated cases in which sickness has reduced the strength necessary to return to work, an order for fourteen daily dinners. Such orders have been granted to nearly one thousand convalescents during the last year.

The Perils of Militia Duty.—The Second and Seventh regiments of the Illinois militia made a trial march and bivouac last week with disastrous results. On going into camp at night the men pulled down vines from walls and trees to make beds of. These being of the *rhus venenata*, the night's sleep resulted in some three hundred active cases of ivy poisoning the next morning for the surgeons to attend. Moral: All green leaves are not laurels of war.—*Boston Medical and Surgical Journal*.

The Iowa Cigarette Law, which prohibited absolutely the manufacture or sale of cigarettes or cigarette paper within the State, or their importation into the State, has been declared unconstitutional by Judge Sanborn, of the United States Circuit Court. His decision followed that of the Supreme Court in the prohibition case some years ago, which was to the

effect that, the federal constitution having delegated to Congress the power to regulate commerce between the several States, the legislature has no power to prohibit the importation of liquors into the State or their sale in the original packages by the importer.

The Green Cross Society has been organized in Vienna, its object being to render medical aid to Alpine climbers and to instruct the guides in the principles of first aid.

A Memorial to Keats.—It is proposed to endow a bed at Guy's Hospital to bear the name of the poet Keats, who was for a short time a medical student there. Guy's is in great financial straits and the ingenuity now being displayed in devising means to replenish its exchequer is worthy of admiration.

A New Local Anæsthetic is called eucaine; it is a synthetic product. It is said to cause anæsthesia of the conjunctiva without affecting in any way the normal reflexes of the pupil.

To Prevent the Introduction of Small-Pox from Cuba.—In answer to an appeal from Governor Mitchell, of Florida, to the navy department, for help in protecting his State against the introduction of small-pox from Cuba, Secretary Herbert has telegraphed instructions to Captain Crowninshield, of the *Maine*, now at Key West, to aid the local health authorities in the work of boarding steamers and passing upon bills of health.

Health in Buffalo.—The mortality in Buffalo for the last six months has been at the wonderfully low rate of 11.67 per thousand. Among the causes which it is claimed have resulted in this reduction of the death rate are frequent examinations of all lodging and tenement houses, the maintenance of a bacteriological laboratory, the sanitary inspection of schools, and especially a strict supervision of the milk supply in order to prevent the sale of milk from tuberculous cows.

The Medical Society of Virginia will hold its twenty-seventh annual session at Rockbridge Alum Springs, on September 8th, 9th, and 10th.

Vital Statistics of Philadelphia.—For the week ending July 18th, there occurred in the city of Philadelphia 595 deaths, of which number more than one-half (315) were among children under five years of age. The most conspicuous causes of death were as follows: Cholera infantum, 121 (20.3 per cent.); pulmonary tuberculosis, 49 (8.2 per cent.); marasmus, 43 (7.2 per cent.); inflammation of stomach and bowels, 39 (6.5 per cent.); convulsions, 26 (4.4 per cent.); apoplexy, 21 (3.5 per cent.); pneumonia, 21 (3.5 per cent.); inflammation of the brain, 20 (3.3 per cent.) There were reported during the week 39 cases of diphtheria, 34 of typhoid fever, and 12 of scarlet fever; and 11, 5, and 2 deaths from the same diseases respectively.

Medical Students in Italy.—In all the universities of Italy, and their name is legion, there are about seven thousand medical students. At the beginning of the summer over two thousand received diplomas with the right to practise medicine.

Reviews and Notices

A PICTORIAL ATLAS OF SKIN DISEASES AND SYPHILITIC AFFECTIONS. In Photolithochromes from Models in the Museum of the Saint Louis Hospital, Paris, with Explanatory Woodcuts and Text. By ERNEST BESNIER, A. FOURNIER, TENNESON, HALLOPEAU, DE CASTEL, FEULARD, and JACQUET. Edited and annotated by J. J. PRINGLE, M.B., F.R.C.P. London: The Rebman Publishing Co., Ltd. Philadelphia: W. B. Saunders. 1896.

WHEN completed this set of plates will be in twelve parts. The third part is now out. We have already given our readers the high opinion we hold of this production. The present fasciculus tends in nowise to diminish the views previously expressed. A good reproduction of the tongue, pathologically altered or otherwise, is beset with difficulties which few have wholly overcome. The frontispiece contains four figures of syphilitic tongues, which are not nearly so faulty in coloring as tongue pictures usually are.

The three remaining plates represent, first, the rather unusual conditions of concentric-ringed eruption of dermatitis herpetiformis, very suggestive of herpes iris lesions, the cockade-like form presented being very striking. Then comes a peculiar-looking gumma of the thigh, the syphilis in which is spoken of as "unknown and unrecognized." The history of this case, which is filled with interest and carries with it an important lesson, is written by Henri Feulard, in whose service the patient was observed.

The last subject (Plate XII.) is discussed by E. Besnier. It represents an old man showing, in separate figures, the two sides of the face, each of which is covered with disseminated lesions of epithelioma of the sebaceous type. One has ulcerated, and the side of the nose is destroyed by a slowly extending and penetrating cancer. This collection is simply one of interesting and instructive cases, with descriptive text written by the physician whose case is depicted. No attempt is made at a systematic treatise on the subject.

POPULAR ESSAYS ON THE CARE OF THE MOUTH AND TEETH. By VICTOR C. BELL, A.B., D.D.S.

THE second edition of this book has appeared so soon that it indeed endorses the contents. The author states that the book has been accepted for instruction by the New York board of education for use in the public schools. No greater compliment could be paid, and we commend the book for its practicability to the profession.

LA SÉROTHÉRAPIE DE LA FIÈVRE TYPHOÏDE, ÉTUDE EXPÉRIMENTALE. Par le DR. M. FUNCK. Bruxelles. 1896.

IN this very interesting and valuable monograph is contained a large number of experimental investigations with regard to the effect of "sero-therapy" in typhoid fever. Notwithstanding the beneficial results which were undoubtedly obtained by this specific treatment in experimentation on animals, Funck says that this mode of treatment should not as yet be applied or even tried in man.

THE METHODICAL EXAMINATION OF THE EYE. By WILLIAM LANG, F.R.C.S. Eng. London and New York: Longmans, Green & Co.

THIS is an excellent work for the beginner and contains all the necessary directions to enable the student to master this difficult procedure.

A TREATISE ON THE MEDICAL AND SURGICAL DISEASES OF INFANCY AND CHILDHOOD. By J. LEWIS SMITH, M.D. Eighth Edition. Thoroughly Revised and Greatly Enlarged. Lea Brothers & Co. 1896.

THIS volume is dedicated very fittingly to Dr. Frederick M. Warner, who was a collaborer in its preparation and died before its publication.

The book comprises nearly a thousand pages and is the outcome of almost a life's experience in hospital and private clinical work, besides having valuable chapters on the surgical diseases in children by Prof. Stephen Smith.

The value of the book is greatly enhanced by such contributions as that of Dr. Joseph O'Dwyer on "Intubation." Professor Robinson has several dermatological chapters and many good illustrations.

In a text-book of this size we miss a chapter on influenza, and the importance of urinary examination is not even mentioned. The book is quite modern, gives a great many points, and certainly deserves a large sale. The type is clear and the illustrations are very good.

ELECTRICITY IN ELECTRO-THERAPEUTICS. By EDWIN J. HOUSTON, Ph.D., and A. E. KENNELLY, Sc.D. New York: The W. J. Johnston Company. 1896.

THIS work is, for the most part, devoted to the explanation of the *modus operandi* of the various apparatus intended for the transmission of electro-motor force to the human body. It is necessarily rather too technical to be understood by the ordinary reader. The therapeutical side of the subject is treated somewhat scantily, which may be regarded as commendable rather than otherwise, since comparatively little is known of this subject, excepting as regards the heating power of the electric current as applied to cauterizing purposes. The laity has great confidence in the mysterious curative virtues ascribed to electricity, and hence in no other method of treatment is greater fraud daily practised. The high scientific reputation enjoyed by the authors is an assurance of the accuracy of their statements. The book has one hundred and twenty-eight good illustrations.

TRANSACTIONS OF THE AMERICAN SURGICAL ASSOCIATION. Vol. XIII. Philadelphia. 1895.

THIS volume, containing the proceedings of the meeting held last year in New York, is full of interesting and practical material. Among the articles of special value are those bearing on the operative treatment of malignant diseases and the use of anæsthetics.

TRANSACTIONS OF THE NEW YORK STATE MEDICAL ASSOCIATION FOR THE YEAR 1895. Vol. XII. Edited for the Association by E. J. FERGUSON, M.D.

THE present volume contains an unusual variety of articles, medical and surgical, proving the well-earned position of the Association as a thoroughly progressive and actively working body.

THE NATIONAL DISPENSATORY FORMULARY. New and Revised Edition. Lea Brothers & Co. Philadelphia and New York.

THIS is a supplement to the National Dispensatory and is a formulary of unofficial preparations. It contains four hundred and fifty-four formulæ for the preparation of various remedies, ranging from acetum aromaticum to vinum rhei, and furnishes a very useful addition to the dispensatory. It is bound in pasteboard.

CONSUMPTION: ITS NATURE, CAUSE, AND PREVENTION. With an Outline of the Principles of Treatment, for all Classes of Readers. By EDWARD PLAYTER, M.D. (and medallist, Toronto University), M.C.P.S. Ont., Author of Playter's Physiology and Hygiene, Editor of the *Canada Health Journal*. Toronto: William Briggs. 1895.

THE object of the work is indicated in the title. It is intended for non-scientific rather than for medical readers, and still the latter will find much to interest them. Consumption is discussed by the author from the many sides which the subject presents, and the social problems it involves are well brought out.

The work is for sale in the States by E. B. Treat & Co., of New York.

THE DISEASES AND TREATMENT OF THE DISEASES OF THE RECTUM. By WILLIAM ALLINGHAM, F.R.C.S. Eng., and HERBERT ALLINGHAM, F.R.C.S. Eng. Sixth edition. New York: Wm. Wood & Co. 1896.

THIS very popular treatise, after being for some time out of print, appears much improved and elaborated in a sixth edition. The different forms of rectal diseases are discussed in an exhaustive and intelligent manner, and many illustrations of typical conditions are scattered throughout the text. The reader will be struck with the thoroughly practical character of the contents, and the very reasonable arguments for the choice of the different operative procedures. This will be noticed more particularly in reference to the commoner diseases of the rectum; for example, hemorrhoids, prolapsus,

and fistula. The criticism of Whitehead's operation is well presented and the objections to its widespread use are well taken. The various operations for hemorrhoids are given in an intelligent manner and will be of great service to the general practitioner, who so often treats these cases. The same may be said of fistula, the true pathological condition of which is so little understood and which is often so injudiciously treated. The importance of a single and proper division of the sphincter is forcibly insisted upon and the after-effect of the neglect of proper precautions in the treatment of the resultant wound and of a proper method of dilatation are very well put. The relative merits of inguinal and lumbar colotomy are practically considered, and tend to enforce the necessity of a proper discrimination in given cases. The radical method of the author in preventing prolapse after the former operation is in our opinion hardly advisable and more experience than that already presented is necessary before the measure can meet with any extended adoption. As a whole, the work is peculiarly adapted to the necessities of the general practitioner as well as the practical surgeon, and will amply repay a careful study.

DIETS FOR INFANTS AND CHILDREN IN HEALTH AND IN DISEASE. By LOUIS STARR, M.D., Editor "American Text-Book of the Diseases of Children." Philadelphia: W. B. Saunders. 1896.

THIS is a bound book of diet sheets, with ingredients for infant feeding indicated and the quantities left blank to be filled in for each case. There are seven forms of blanks for the different ages. Owing to the "compact binding" it has been found necessary to insert instructions as to how to tear out the leaves without tearing them across. Since the main object of the book is to have these readily removable, the binders might have done their work in a less "compact" manner. The scheme is a good one, but it has been rendered almost impracticable in the present edition by too much binding. The paper tears less readily along the perforated lines than elsewhere.

THE TRAINED NURSES' DIRECTORY, May, 1896. Compiled and Edited by M. LOUISE LONGEWAY, Graduate of the New York Training School, Bellevue Hospital. Published semi-annually.

THIS is a collection of names carefully selected by prominent physicians of New York and vicinity from their private lists, and has been endorsed by many well-known practitioners.

Being of vest-pocket size and with flexible cover, it is well suited for the physician to have with him when he needs to refer to the list. It is arranged by schools and by streets, and has blank sheets for memoranda. Many excellent nurses are omitted from the first issue, but the next promises to be more complete. The venture has a worthy object and should succeed.

ŒUVRES DE LÉON LE FORT, PROFESSEUR DE CLINIQUE CHIRURGICALE À LA FACULTÉ DE MÉDECINE DE PARIS, ETC. Publiées par le DR. FÉLIX LEJARS, Professeur Agrégé à la Faculté de Médecine, etc. Tome Deuxième, "Chirurgie Militaire; Enseignement," avec une préface de M. le Médecin Inspecteur-Général DUJARDIN-BEAUMETZ, Félix Alcan, Editeur. Paris. 1896.

THIS second volume of Professor Le Fort's extensive work makes a book of nearly a thousand pages. It is devoted chiefly to a consideration of military surgery, though the subject of instruction occupies an appropriate space. In a preface Dujardin-Beaumetz renders the author worthy homage. The volume is marked by the same proofs of profound study and devotion to the cause which has always characterized the numerous writings of this distinguished author.

The third volume, which will complete the work, is shortly to be issued and will be devoted to surgery proper.

THE TREATMENT OF PHTHISIS. By ARTHUR RANSOME, M.D., M.A. Cantab., F.R.S. London: Smith, Elder & Co. 1896.

THIS volume will be found to be a very practical addition to the literature of this very common disease and will be appreciated by every student anxious to analyze facts, draw deductions, and enlarge his personal resources in the treatment of the various complications and conditions of this dreaded disorder. No specific is given, but the whole subject is treated from a broad and rational standpoint.

Society Reports.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 12, 1896.

JOHN SLADE ELY, M.D., PRESIDENT.

DR. IRA VAN GIESON presented a preliminary report on some studies he had made on

The Explanation of True Heterotopia of the Spinal Cord.—He said that by heterotopia of the spinal cord was meant a dislodgment of portions of the gray matter situated outside of the outlines of the posterior or anterior horns. Pick, in 1878, had first drawn attention to this condition, and had published a case in which he had found exceedingly minute masses of gray matter which had become displaced and were situated near the middle of the posterior columns. In a second case published a year or two afterward he found the same condition, to which he gave the name "heterotopia." After these cases had been placed on record a number of others had been published in which all sorts of displacements had been described, but many of these were afterward found to be really due to bruising of the spinal cord. The speaker said that he had reported two genuine cases, and that up to the present time there were only about six cases on record. The displaced portion was usually situated about the middle of the posterior columns. To understand what he considered to be the true nature of this condition, reference must be made to what are known as "outlying cells." In 1873, Beisso, an Italian, had shown that in the spinal cord of some of the lower animals, particularly in oxen, the ganglion cells were not confined to the gray matter. Sherrington had carefully studied these outlying cells in the human spinal cord. He found that they occurred in three regions, viz.: (1, and most frequently) on the internal surface of the posterior horn; (2) on the outside limb of the posterior horn; and (3) just at the junction of the anterior and posterior horns, where they join the lateral columns. Dr. Van Gieson said that he had found them in a fourth region—in the region of the anterior commissure. In his opinion heterotopia was simply a clustering together of these outlying ganglion cells. A study of the development of the nervous system showed that this whole system originated from the outer of the three germ layers—the ectoblast. The first stage of development consisted in a thickening of the dorsal aspect of the embryo, the cells of the ectoblast becoming a little thicker. Next, there was a dipping in of the ectoblast, forming what was called the primitive furrow. This was followed by a slight division between the ectoblast and the primitive furrow. To this the name of "neural crest" had been given, because from these crests arose the spinal ganglia. In the next stage of development the primitive furrow became deepened and cup-shaped, and the edges of the cup tended to approach each other. A continuation of this process resulted in the formation of a tube—the future canal of the spinal cord. Then the neural crest became spread over the spinal cord, and subsequently divided in two, these halves being situated on the sides of the spinal cord. These lateral halves then spread until they almost reached the anterior portion of the spinal cord. The cells which originally came from the spinal ganglia sent their processes into the spinal cord. As the cells of the primitive medullary canal migrate outward to the periphery of the spinal cord they become pear-shaped, forming the neuroblast, the future ganglion cells. It should be particularly noted that the development of these ganglion cells was in

a radial direction. From the radial growth of the ganglion cells and the constant encroachment on the gray matter of the posterior root collaterals and other fibres, some of these cells are thrust out beyond the confines of the gray matter and become the outlying cells; hence these displaced masses of gray matter are simply a grouping together of the outlying ganglion cells—in other words, an exaggeration of a normal condition. Heterotopia is observed, the speaker said, to the greatest extent in those regions in which were to be found the greatest number of outlying cells. The chances of these heterotopic masses forming a nidus for tumors seemed to him extremely small.

DR. JAMES EWING remarked that it was pleasant to learn that three out of the six genuine cases of heterotopia on record had been discovered by Americans.

Tumors of the Brain.—DR. J. S. THACHER made some remarks on this subject, illustrating them by lantern slides. He said that tumors of epithelial origin appeared in medical literature much less frequently than formerly. A considerable number of these epitheliomatous tumors had been shown to be sarcomata or endotheliomata. It was natural that true epithelial tumors should not be frequently met with in the brain, because the cells of the nervous system, although originally derived from the epiblast, had so far lost their resemblance to ordinary epithelium that only those growths starting from the lining epithelium of the central canal would show in neoplasms a structure which was distinctly epithelial. Very few cancers of the brain had been reported in recent years. Knapp had collected forty cases coming under his personal observation, and of the thirty in which the nature of the growth was recorded not one was cancerous. Dr. M. Allen Starr, in a collection of two hundred and sixty-nine tumors of the brain occurring in persons under twenty years of age, and in which the nature of the growth was recorded, found only ten to be cancerous, and most of these were secondary. The speaker then illustrated by lantern slides the nature of the growths found in four cases of primary carcinoma of the brain. These all contained cylindrical cells. Two of them were secondary to tumors elsewhere in all probability; one was in a stage of what could be called properly only epithelioma; and one was a tumor which had apparently begun in the brain and had gone on to multiple metastatic deposits.

The first slide exhibited was from a tumor of the brain secondary to a growth in the stomach. It had been taken from a man, fifty-five years of age, who had come into Dr. Murray's service at St. Luke's Hospital, complaining of pain in the shoulder. A tumor was found in the scapula which on examination proved to be an adeno-carcinoma. Dr. Thacher said that, thinking it appeared to be secondary to a tumor of the alimentary canal, he had asked if there had been any symptoms pointing in this direction, but he had received a negative reply. During the last two weeks of life the man had complained of pain in his head; the right pupil had been contracted, and there had been incomplete left hemiplegia. There were no symptoms of gastric trouble. The autopsy revealed a large tumor of the stomach to the left of the cardiac orifice; several smaller tumors in the right lung; a large tumor involving a portion of the scapula, and two tumors in the brain—one in the frontal lobe, one and a quarter inches in diameter, and one in the posterior part of the parietal lobe, one-half inch in diameter.

The second specimen was from a woman, forty-five years of age, in Dr. Northrup's service at the Presbyterian Hospital. Six months previously she had fallen and had had convulsions, followed by some difficulty of speech and complete loss of power in the left arm and

leg. She had recovered speech and the paralysis had improved. About two days before her death there had been some rigidity of the neck. She had then passed into coma. At the autopsy a tumor was found in the right parietal lobe just behind the fissure of Rolando. It measured two inches in diameter and involved the cortex, but did not reach the ventricle. It contained viscid material. In the lung was a tumor about half an inch in diameter. No other tumors were found. From its alveolar structure, the fact that the alveoli contained much mucin, that they were lined with cylindrical epithelium, that the tumor did not communicate with the ventricles, that it was apparently not connected with the membranes of the brain, and that there was a small tumor in the lung, he felt justified in concluding that this tumor was secondary to the nodule in the lung.

The third specimen was from a girl, sixteen years of age, who entered Dr. Ball's service at St. Luke's Hospital, complaining of vomiting and headache. She suffered from these attacks for two months or more before death. There were no other prominent cerebral symptoms, and she was supposed to be suffering from gastritis and hysteria. The vomiting occurred several times a day, and did not appear to depend upon the taking of food. About seven hours before death she complained of pain in the head being extremely severe, and she was more than usually irritable and noisy. Then there was a general rigidity lasting about an hour, and finally general tonic convulsions with cyanosis. At the autopsy, along the upper and inner edge of the right temporal lobe and along the floor of the descending horn of the lateral ventricle and invading the brain tissues in the immediate neighborhood, was a new growth measuring two inches by one by one inch. Its consistency was like that of the brain. It involved the right optic thalamus and corpora quadrigemina. There were no other tumors. The growth consisted of very regular cylindrical cells covering the papillæ. From the fact that there was no other tumor, from its distinctly papillary character, from the regular cylindrical cells, and from its situation at the border of one of the ventricles, the conclusion seemed inevitable that this was a primary papilloma of the choroid plexus and the descending horn of the lateral ventricle.

The fourth specimen was from a man, forty-five years of age, who came into Dr. Thompson's service at the Presbyterian Hospital about eight months before his death. He stated that four months before admission he had begun to suffer from lumbar pain, and three months later from prickling and numbness in the legs and thighs quickly followed by weakness. Then a marked "girdle" sensation had been felt about the waist. Over the trunk and legs was a marked reduction to sensibility, pain, and temperature. During the last month of life he became very dull. The autopsy showed a tumor encircling the cord and invading the eighth and ninth dorsal segments, and destroying all of the cord at that level except a little anteriorly. There was a small nodule in the lung, and in the brain were eleven tumors varying from half an inch to one and a half inches in diameter. These tumors were very vascular and papillary, the papillæ being covered with cylindrical epithelium. The tumor in the spinal cord had given rise to the clinical picture observed. It was conceivable that these numerous tumors in the brain and the one in the spinal cord might have been secondary to the tumor in the lung, which was about three-fourths of an inch in diameter. Clinically it would appear that the tumor of the spinal cord was not the primary one, yet in the four cases reported it had been shown that a considerable neoplasm might exist in the brain without clinical symptoms. From the fact that the largest tumor in the body was in the

brain, and was in the descending horn of the lateral ventricle, where two or three tumors had been recorded, and from the vascularity and papillary character of the tumors, he thought it was safe to conclude that the tumor began as a papilloma of the choroid plexus of the descending horn of the lateral ventricle, and afterward passed into the category of carcinomata.

DR. A. JACOBI asked why Dr. Thacher had suspected in the case of the adeno-carcinoma of the scapula that there was also a tumor of the alimentary canal.

DR. THACHER replied that the regularity of the cylindrical cells and the mucous contents of the alveoli were probably the most striking features which had led him to think there might be a tumor in the alimentary canal.

THE PRESIDENT said that he thought a metastatic tumor often preserved a suggestion of the structure from which it had developed. He had noticed this particularly in adenomata of the breast and of the stomach. In the former there was very frequently a distinct suggestion of a compound tubular gland preserved, although the growth might be extremely irregular in other respects and abundant. In the stomach he had noticed a preservation of the type of a simple cryptic gland.

DR. WOOD exhibited under the microscope sections from a

Tumor of the Cerebellum.—These sections had been taken from a patient who had been admitted to the St. Luke's Hospital to Dr. Kinnicutt's service about two weeks before death. There had been cough and pain in the left side before admission, and on entering the hospital bloody fluid had been found in the pleura from which nearly a pure culture of tubercle bacilli had been obtained. About one week later the man had become comatose, and this condition had been associated with rigidity of the muscles of the arm and some hyperæsthesia. At the autopsy the pleura was found to be very much thickened, there were a few old cicatrices in the lungs, and a number of pale yellowish nodules scattered through the brain—two or three in the cerebellum, two or three in the cerebrum, and one in the optic thalamus. There was no new growth in the alimentary canal. The tumor of the cerebellum was thought to be an endothelioma, (1) because the cells were developed in the perivascular lymph spaces, and (2) because the growth had a distinctly tubular character.

DR. THACHER said that at the autopsy he had felt positive that these were masses of tubercle, but the structure seen under the microscope certainly resembled carcinoma. As only one nodule had been examined microscopically he could not say whether the growth was endothelial or epithelial.

The society then went into executive session.

— — —
Stated Meeting, February 26, 1896.

Lesions of the Heart and Blood-Vessels.—DR. GEORGE P. BIGGS presented four specimens illustrating sudden death due to occlusion of the coronary arteries. The first one was from a man, twenty-five years of age, a cooper by occupation. Alcoholism and syphilis were denied. The patient after going up a flight of stairs walked into a friend's room and sat down. After talking for a few minutes his head suddenly fell upon his chest, the breathing became rapid, and the face cyanotic. He was speechless and could not be aroused. The ambulance arrived about fifteen minutes later, and then the breathing was slow, irregular, and shallow, and there was no perceptible radial pulse. On admission to the hospital his breathing was shallow and irregular, he was cyanotic, and the

pulse could not be felt. After free stimulation he revived sufficiently to answer a few questions. He stated that he had not been drinking for a year past, that he had no pain, and that he was extremely thirsty. In spite of the cyanosis there was no feeling of suffocation. He soon relapsed into unconsciousness, and œdema of the lungs developed very rapidly. He died about an hour and a half after the development of the first symptoms. At the autopsy rigor mortis was well marked; there was no œdema; the diaphragm was at the level of the fifth space on the right side and the sixth space on the left. The heart was found very greatly distended with blood, which was dark in color and largely fluid. The cavities of the heart were dilated and the walls correspondingly thin. The heart muscle was rather soft but of normal color. The valves were normal except for slight thickening at the bases of the mitral and aortic cusps. There were several elevated, yellowish areas of atheroma in the aorta, two to five millimetres in diameter. Attached to two of these areas in the anterior portion of the aorta just above the aortic valve were two thrombi. The larger one of these was attached near the opening of the left coronary artery by three small finger-like projections only, and was irregularly cylindrical in shape, measuring one and a half by one-half centimetres. It was found lying in the most anterior sinus of Valsalva, completely filling it, and causing the aortic cusps, back of which it lay, to remain in the close position. More careful examination revealed that the left coronary artery, which arose from this sinus of Valsalva, was completely closed over by the thrombus. The second thrombus was half a centimetre in diameter, and was attached loosely a little above the first one. The coronary arteries were moderately atheromatous. The kidneys showed slight chronic diffuse nephritis.

The speaker said that the case was interesting as showing how easily the cause of death in such a case might be overlooked. The smaller thrombus had fallen off, notwithstanding the care taken in the removal of the heart, and was found only after careful search of the blood left in the pericardial sac. The larger thrombus, the one obstructing the coronary artery, was so loosely attached that it dropped off during the incision of the heart, and if the aorta had not been inspected from above before making the incision the position of the thrombus would have been entirely overlooked. Apparently the thrombi had been in existence for a considerable time, but had caused no trouble, as they had been regularly washed upward by the blood current. For some reason the larger one had suddenly fallen backward and occluded the left coronary artery, thus causing the sudden cardiac failure.

The second specimen was from an autopsy made some time ago for Dr. Robert Milbank. The patient, a male of thirty-one years, gave no history of syphilis, rheumatism, or malaria, and had enjoyed good health with the exception of attacks of what were described as "painful dyspepsia." He had recently taken a good deal of violent exercise. At 2 p.m. on the day of his death he had taken a hearty lunch with a friend at the club, and at 4 p.m. had been seized with severe epigastric pain. When seen by Dr. Milbank he was suffering intensely and was only temporarily relieved by the hypodermic injection of large doses of morphine. After an hour or two some watery mucus was vomited. The pulse was small and rapid—110 to 124. The patient was conscious almost to the last, and walked across the room shortly before death. He died about six hours after the first symptoms. The autopsy revealed an embolus of considerable size, lodged in the left coronary artery. In the aorta were two small thrombi, one attached just at the

mouth of the left coronary artery, the other attached a little higher up. A considerable portion of the thrombus at the mouth of the left coronary artery was missing, and was undoubtedly the source of the embolus in that vessel. There were no thrombi in the heart cavities. The organ was of normal size, and its valves were normal. There was an endarteritis of the aorta, apparently rather acute in character. The sub-pericardial adipose tissue was rather thick, particularly over the right ventricle. The other organs of the body showed no important lesions.

The third specimen was from a sailor, forty-eight years of age. Two days before admission to the hospital, while lifting a heavy weight, he had been suddenly seized with severe pain referred to the left hypochondriac region. This was soon followed by dyspnoea, and both pain and dyspnoea had been constant since that time. The pulse was found to be very irregular and feeble, the face extremely congested, and the feet were slightly œdematous. No cardiac murmur was audible. The respirations were rapid and feeble, and moist râles were heard over both sides of the chest, anteriorly and posteriorly. His temperature was 101.4° F., respirations 56, and pulse 100. Notwithstanding free stimulation he died a few hours after admission and two days after the onset of the symptoms. At the autopsy the body was found to be very obese; rigor mortis was very marked; the diaphragm was at the sixth rib on the right side and the sixth space on the left side. Each pleural cavity contained six hundred cubic centimetres of serous fluid, and the pericardium seventy-five cubic centimetres of serous fluid. The heart was very greatly enlarged; its cavities were all very much dilated and distended with partially clotted blood. There was slight hypertrophy of the left ventricle. The valves of the left side were very slightly thickened, but no incompetence could be detected. An ante-mortem thrombus completely filled the left auricular appendix, and a second thrombus, measuring two centimetres by one centimetre was attached in the apex of the left ventricle. The most anterior sinus of Valsalva was completely filled with an ante-mortem thrombus, which held the cusp completely closed. This thrombus covered over the opening of the left coronary artery, and was continuous with a similar clot which filled the coronary artery almost completely for three centimetres. The primary site of the development of this thrombus was apparently in the aorta very near the opening of the coronary artery. The aorta and coronary arteries were moderately atheromatous. The muscular substance of the heart was soft, pale, and friable throughout. The lungs were extremely œdematous. The spleen was normal. The kidneys showed a moderate amount of chronic diffuse nephritis. The right one contained a recent infarction, one centimetre in diameter. The vessels at the base of the brain were moderately atheromatous. The other organs were practically normal.

The speaker said that it was probable that the dyspnoea and feeble irregular heart action which suddenly developed shortly before death were due to a more complete closure of the left coronary artery. This obstruction was probably developed rather slowly, so that the disturbance of the heart action was not so marked as in the other cases.

Rupture of the Heart with Myomalacia.—For the fourth specimen Dr. BIGGS said he was indebted to Deputy Coroner O'Hanlon, who performed the autopsy. It had been removed from a man of sixty years who, for a year or more, had been troubled with indefinite precordial oppression and occasional attacks of angina. On the day of his death he went out feeling as well as usual, but was suddenly seized with a severe attack of angina just as he reached his desti-

nation. He succeeded in mounting a flight of stairs, but died almost instantly after doing so. At the autopsy the pericardial sac was found distended with blood. The heart was of normal size and was covered with considerable adipose tissue. Just at the junction of the outer wall of the left ventricle with the inter-ventricular septum was a large, ragged tear, about two centimetres in length. The cardiac muscle around this area was softened and torn. From this point of rupture the course of the blood was traced almost directly outward to the visceral layer of the pericardium. It then dissected its way upward to the base of the ventricle, lifting up the pericardium and forming a large hamatoma over the entire base of the left ventricle. The final rupture was shown by a linear ragged tear of the pericardium, about two centimetres long. The valves and the coronary arteries were very atheromatous. About one centimetre from the origin of the right coronary artery the lumen of the vessel was very materially encroached upon by atheromatous deposit, and finally completely occluded by a recent thrombus. The rupture occurred in the particular area supplied by this artery and was the result of myomalacia following its obstruction. Dr. Biggs referred to a recent article in the *Journal of Experimental Medicine*, in which Porter described some experiments he had made on dogs by ligating or partially occluding the coronary vessels. This experimenter's conclusions in part were: (1) That the frequency of the arrest of the heart as a result of this occlusion depended upon the size of the vessel ligated; (2) that the rapid closure of a coronary artery was invariably followed by death of the part it supplied, and that the process was a typical coagulation necrosis; (3) the disturbed action of the heart and final arrest he attributed to the disturbance of the co-ordination of the heart, due to the anæmia of a considerable portion of the heart muscle. On the passage of a glass tube down through the innominate into the coronary artery he noted invariably an almost immediate development of irregular heart action with a weakening of the contraction and lowering of the arterial pressure. If this occlusion were allowed to continue, the heart very soon became arrested. If the glass tube were soon removed, the symptoms disappeared and the heart's action returned to its normal state, showing that it was the anæmia of the part supplied which had disturbed the mechanism. By connecting the end of the glass tube with a supply of defibrinated blood diluted with salt solution, and supplying in this way nutrition to the area thus obstructed, he was able to keep up the normal action of the heart for a long time, thus demonstrating that the presence of the foreign body was not itself responsible for these symptoms. Cases of complete coronary obstruction, the speaker said, were rarely observed clinically, and still more rarely diagnosed, owing partly to the suddenness of death and the variability of the symptoms. The clinical picture usually presented is briefly as follows: Rapid, irregular, feeble heart; dyspnoea and pulmonary œdema, with or without precordial pain. The absence of pain was a characteristic feature of the first case presented, while in the second case the pain was described as "intense," and in the third and fourth cases as "severe." An interesting feature of the first two cases was the comparatively early age, twenty-five and thirty-one years, a period of life when coronary lesions are not usually expected.

The next specimen exhibited was one showing extensive replacement of the muscular tissue of the left ventricle by fibrous tissue. This was due to a gradual occlusion of the left coronary artery by atheromatous and calcareous changes. As the specimen had been previously presented to the society, it was shown

only as an illustration of the possible remote effect of coronary obstruction.

Ulcerative Endocarditis.—The last specimen in this series was one from a case of ulcerative endocarditis. It had been removed from a man, thirty-seven years of age, who had been well up to nine days before his admission to the New York Hospital, when he had had a chill. On the second day of his illness he was feverish, and suffered from shortness of breath and pain in the left side. He then developed also cough with mucous expectoration. A second chill occurred on the sixth day. On admission his temperature was 104° F., respirations 40, and pulse 120. Physical examination showed an area of dulness with bronchial voice and breathing on the left side opposite the angle of the scapula and near the spinal column. The heart action was regular, rapid, and strong. The urine contained a trace of albumin with granular casts. The patient improved under stimulation and tonic treatment up to the twenty-first day of his illness, when the temperature suddenly rose to 105.3° F. For some days previously it had been below 100° F., and his pulse had been between 72 and 80. The temperature soon subsided, was lower for four days, when another chill occurred, with a temperature of 104° F., followed by profuse perspiration. The blood was examined for malarial plasmodium, but none was found. After this time chills were of frequent occurrence, and were associated with profuse perspiration and a septic type of fever, the temperature frequently rising to 106° or 107° F., and often falling to normal. Prostration rapidly increased, and he died during the tenth week of his illness, and in the sixth week after the development of symptoms of general sepsis. The autopsy revealed abundant adhesions over the left lung, and a few over the right lung. The heart was about normal in size; its cavities were dilated and greatly distended with blood; the muscular substance was pale and soft; the mitral and pulmonary valves were normal. Two of the aortic cusps were normal, while the third had attached to the lower two-thirds of its inferior surface a large amount of grayish coagula. Three ragged perforations, the largest four millimetres in diameter, through this aortic cusp were found in the area with which the thrombi were connected. Examination of the cusps from above showed no vegetations, but there was conclusive evidence of the development of a large aneurism of the valve prior to the rupture. The tricuspid orifice was almost completely filled with firm, whitish thrombi, which were attached to the superior surface of the valve. The largest thrombus measured two and a half centimetres in diameter. All the thrombi were solid throughout. Examination in the fresh state and by cultures showed large numbers of capsule diplococci. A large part of the lower left lobe of the lung was still consolidated. There were a few areas of infarction in the upper lobe, and thrombi were present in many of the pulmonary vessels. The right lung contained infarctions, and the vessels leading to those areas were occluded by thrombi. The spleen was slightly enlarged and soft, but contained no infarctions. Both kidneys showed moderate parenchymatous degeneration; the right one contained an infarction.

THE PRESIDENT said that only a short time ago he had seen a review of a German article which stated that experiments like those described had been tried on dogs and rabbits. In this article it had been asserted that total occlusion of the coronary arteries caused complete arrest of the heart in about two minutes, and that if the occlusion were complete for a short time only and the blood then readmitted to the vessels the heart would recover. The specimen of interstitial myocarditis was of extreme interest in connection with the subject of aneurism of the heart.

Double Aorta and Dissecting Aneurism.—DR. WILLIAMS, of Buffalo, presented a specimen of double aorta and dissecting aneurism. The patient, a man of fifty-eight years, had been under the care of Dr. Charles G. Stockton, who had first seen him on September 27, 1894. The patient said he had never been sick up to eight years before, when he had had a severe attack of pneumonia. The previous winter he had had some shortness of breath and tumultuous heart action, and since then more or less dyspnoea on exercise or excitement. His height was five feet nine inches, and his weight two hundred and sixteen pounds. He presented a distinctly livid appearance: the pulse was weak and irregular; the capillary circulation was poor; there were dry cough and scanty mucous expectoration. Physical examination showed emphysema of both lungs with congestion at the bases. There was a systolic bruit at the apex of the heart, conveyed far to the left. The impulse was diffused and scarcely perceptible. When lying down the patient's face became greatly congested. One month before this time this man had successfully passed an examination for life insurance. It was found that he voided eighteen hundred and twenty-four cubic centimetres of urine in the twenty-four hours, which contained 17.8 grams of urea, that the specific gravity of the urine was 1.010, and that it was free from sugar and indican. Under treatment with digitalis, hot-air baths, and faradization, his general condition improved considerably. One morning he was found dead in bed without having made any complaint during the night. The autopsy was made about twelve hours after death. Rigor mortis was firm. The subcutaneous fat was three-fourths of an inch thick over the thorax and two inches thick over the abdomen. There was a quantity of bloody serum in the left pleural cavity, and a large firm blood clot. The left pleural cavity was full of clotted blood; the right pleural cavity was empty. The heart was very large, its muscle thick and firm, and there was hypertrophy and dilatation, especially of the left ventricle. The mitral orifice admitted two fingers. The valves were stretched, but not thickened. There was moderate atheroma of the ascending aorta. The left kidney was large, firm, and contained several small cysts. The capsule was somewhat adherent, and the surface beneath granular. The right kidney presented a similar condition. The kidney showed under the microscope the changes of chronic diffuse nephritis. The spleen and liver were normal; the stomach was small; the large intestine and vermiform appendix were normal. The upper and posterior wall of the aorta exhibited an opening one-fourth of an inch in diameter and nearly round. It was supposed at first to communicate with the descending aorta, which had ruptured into the pleural cavity. The aneurismal dissection in the thoracic aorta appeared to the left and in front, extending behind beyond the middle line to the right. Between the tenth and eleventh intercostal arteries it was far over to the right and behind. At the level of the renal arteries it had travelled still farther around, and a little below this point it entirely encircled the pair of aortic trunks to be subsequently described. It reached to the bifurcation of the aorta, and on the right common iliac to its bifurcation into the external and internal iliacs. The opening below the left subclavian artery did not communicate directly with the aneurism, but with a vessel which was continuous with the left common iliac. What had been supposed to be the only aorta was continuous with the right common iliac. The dissecting aneurism surrounded both vessels more or less completely. The aneurism had its origin in a rupture, not of the main artery but in a channel to the left of it. It had stripped off the pleura on the left side and had broken

through this, causing the fatal hemorrhage into that cavity.

A careful examination showed that there was a duplication of the aorta from the left subclavian down, the two portions being separated by a complete septum. The right was the larger and was in line with the descending limb of the arch. The left branch did not exhibit arterio-sclerosis. The principal vessels arose from the right branch, except the anterior mesenteric, which was given off from the left and behind. The celiac axis, superior mesenteric, and both renal arteries arose from the right or principal branch. There were ten pairs of intercostal arteries arranged along the right aorta, most of them patulous. Many of the intercostals opened from the right aorta into the left, and went no farther.

Dr. Williams said that this condition was very rare. Krause cited five examples of double aorta. In view of the fact that in the development of the human embryo the right and left systems of arterial arches fuse together at a very early period, it was astonishing that the man should have lived to a good age in health and comfort.

Rupture of the Aorta.—DR. JAMES EWING presented a specimen of rupture of the aorta removed from a woman twenty-six years of age. She presented no personal or family history of importance. The illness had begun three years before death with the ordinary symptoms of acute nephritis developing after exposure to cold. It was characterized at the onset by œdema and dyspnea. These symptoms continued irregularly for about one year, after which uræmic symptoms were added. She entered the hospital on January 27th and was then pale and cyanosed. There was a paralysis of the right side of the face which had appeared three months before. The pulse was 100, somewhat irregular, and showed remarkably high tension. There was severe and constant headache, and a constant feeling of sinking and choking about the heart. She was given the usual remedies for reducing arterial tension without much effect, and they were finally stopped. Within two hours after discontinuing the use of arterial dilators, she complained of severe pain in the chest and became greatly prostrated. The house physician then found in addition to the loud systolic murmur, heard all over the precordium, a remarkably harsh double murmur, heard loudest over the aortic valve. The patient went into collapse, and died within an hour. At the autopsy the kidneys were found to be of about the normal size, the surface was coarsely granular, the capsules non-adherent, the cortex irregular in thickness, the markings obliterated, and the kidney tissue in part replaced by uric-acid infarcts. There was very little congestion of the kidney. The heart was moderately enlarged. The wall of the left ventricle was very considerably hypertrophied without dilatation. There was no roughening of any of the valves, and there was only very slight atheroma. On opening the pericardium a large amount of fresh bloody serum was evacuated. The heart was surrounded by a thick dark clot. Some difficulty was experienced in finding the origin of the blood, so the abdominal viscera were removed and the aorta stripped up. On reaching the aortic valve the finger was passed into a peculiar pouch. About one inch above the aortic cusps was a clean linear rupture of the whole aortic wall, and through this rupture the blood had infiltrated the tissues around the aorta, and, rupturing into the pericardium, had infiltrated the tissues of the aorta to the middle of the transverse arch. At the origin of the left subclavian artery could be seen a healed partial rupture of the subclavian vein, about three-quarters of an inch in length, which appeared as if the intima and media had been slightly displaced on the adventitia. The remainder of the aorta showed very little atheroma.

The speaker remarked that at least two such cases had been reported to the society within the past few years.

DR. GEORGE P. BIGGS said that about a year and a half ago Dr. Ferguson had presented to the society a specimen showing a vertical linear rupture in the aorta, situated just a short distance above the aortic valve. In this case the blood, after having dissected along the aorta nearly its entire length, had finally broken through into the pericardium, causing sudden death.

DR. VAN HORNE NORRIE recalled a case of rupture of the aorta, seen about two years ago in a male patient in St. Luke's Hospital. This man was suffering from phthisis and nothing unusual had been noticed until about half an hour before his death, when, after a sudden attack of pain around the heart he went into collapse and died. The autopsy showed complete transverse rupture of the aorta about one inch above the aortic orifice, and a large amount of blood in the pericardial sac. The gross appearance of the aorta was normal.

DR. EWING said that Dr. Delafield thought that the primary cause of the rupture in the case he had just reported had been the high tension of the arteries. From the gross and microscopical appearances of the specimen presented, it was evident that the rupture had not been due to the giving way of a cicatrix of syphilitic origin.

The society then adjourned.

Clinical Department.

A CASE OF FATAL TRAUMATIC MYOCARDITIS (?).

By R. VAN SANTVOORD, M.D.,

NEW YORK.

THE following case presented from the standpoint of pathology so many points of interest upon which little light is shed by recent literature, in addition to its medico-legal importance, that it seems worth reporting, although, in the absence of an autopsy, it is unfortunately incomplete.

L. Z—, aged twenty-four, an engineer by occupation, had consulted his physician, Dr. G. W. Oakes, of Williamsbridge, a few days before the accident about to be narrated, for a trifling derangement of digestion. He was otherwise well and able to attend to his work. On June 1, 1894, a wagon in which he was riding was struck by a trolley car and he was thrown violently to the pavement. Just how he fell I was not able to ascertain. He was taken to a hospital and ten days later to his home, where he was attended by his own physician. On July 2d I saw him in consultation and found the following: He was seated with his elbows resting on a table in front of him, suffering from great dyspnea. There were old ecchymoses about the right side of the head and face. The pulse was feeble, regular, beating 136 per minute. The heart was not appreciably enlarged or dilated. Its sounds were weak but normal. There were a few moist râles over the lower lobes of both lungs. The legs and feet were very œdematous. There were no fractures of ribs or evidences of intracranial injury. I was informed by his physician that the symptoms had been the same, though at first not so intense, during the period of his attendance since the accident and the patient was said to have suffered similarly in the hospital, though of this part of the history I could get no satisfactory account. On July 5th death occurred from cardiac exhaustion.

We have here a case of fatal cardiac lesions, the exact nature of which was not self-evident, resulting from traumatism, but without any penetrating wound.

An erroneous statement that a diagnosis of fracture of the base of the skull had been made at the hospital led me to consider first the possibility of some nerve lesion. Rapid heart action has been observed in cases of lesions of the medulla, presumably from paralysis of the pneumogastric or by pressure upon the latter by tumors in the thorax. Neither in the one case¹ nor in the other² does the rapid heart action imperil life. In Bouveret's article on paroxysmal tachycardia³ several fatal cases of this disease are recorded and the theory is advanced that the disease is due to the exhaustion of the cells of the bulbar centres of the vagus. In the only case among those which Bouveret regards as typical of this malady, that of Bristow,⁴ death did not occur during a paroxysm and no lesion of the nervous system was found, but the heart was much dilated. In view of the facts that in cases of demonstrated lesions of the medulla and of the pneumogastrics, the heart's action has not been so rapid as to imperil life, and that the only case in which an autopsy has been recorded in a case of paroxysmal tachycardia a lesion of the myocardium was found, the statement that there may be a lesion of the vagus centre or of any other nerve centre which betrays itself by dangerously rapid cardiac action seems at least unproved. In such cases a lesion of the myocardium seems much more probable, in the light of our present knowledge. These considerations led me to think of the probability of the existence of a lesion of the myocardium in my case.

A considerable number of cases of injury to the heart due to non-penetrating injuries have been collected by Fischer⁵ and Schuster.⁶ More or less extensive lacerations and ecchymoses of the heart muscle with or without injuries to the aorta and other organs are related, death being caused by shock, hemorrhage, traumatic aneurism, or secondary inflammations. In only eleven of eighty-two cases collected by Schuster did the patient survive more than twenty-four hours.

Two highly suggestive cases are recorded by Hochhaus.⁷ The first was that of an adult, forty-three years old, previously healthy, who fell from a wagon, breaking some ribs, though not in a locality involving injury to the heart. His heart later was found to be somewhat dilated, pulse 100-120, small and soft. He became premanently disabled on account of his cardiac malady. The second was a similar though more complicated case resulting from a fall on the back. Both were regarded as cases of chronic myocarditis of traumatic origin.

It is to this class of cases of injury to the heart muscle due to non-penetrating injury that the case above narrated probably belongs. The lesion is supposed by Schuster to be caused by concussion or by the direct crushing of the heart between the sternum and the vertebrae, the latter springing back into place. It seems not impossible that cardiac laceration may be produced by spasmodic contraction excited by the shock of the accident, as occurs not infrequently in the case of the voluntary muscles.

In looking over the recent literature of this subject I could find very little about the matter. It is not probable that such cases are extremely rare. It is not improbable that traumatism has a larger share than is generally recognized in chronic diseases of the myo-

cardium, as exemplified by the two cases related by Hochhaus above referred to. The effect of traumatism on the cardiac valves has long been recognized. I publish this case in the hope that it may attract attention to the less readily recognized lesions of the myocardium due to injury and lead to the publication of illustrative cases.

106 WEST ONE HUNDRED AND TWENTY-SECOND STREET.

A CASE OF GLOSSITIS.

By W. WASHBURN, M.D.,

NEW YORK.

J. M. H.—, aged forty-five, commercial traveller, had generally enjoyed good health, but had been subject to what had been termed malarial attacks, for which he had been treated by quinine. About December 1st the patient discovered a small ulcer on the inside of the left cheek, which after washing with witchhazel disappeared. He had not had syphilis.

On December 5th the patient presented himself at my office for treatment for sore throat and pain down the left side of the neck. He was well nourished, rather fleshy. The skin was of good color and the eyes were clear. The pulse was 90, temperature 100° F., respiration 22. The left tonsil was enlarged slightly, with marked redness, localized on the anterior inferior surface. I ordered a gargle of tannic acid and potassium chlorate. Early the following morning I was summoned in haste, the messenger saying that the patient was choking to death. When I reached the patient he was in bed, conscious but unable to speak, and had a feeling as though he could not breathe. The nose was, however, free and with a little encouragement he soon learned that he could not only breathe properly but also swallow without any great difficulty. The mouth was forcibly open and the tongue filled the whole opening, the teeth being embedded in the tongue. Closer examination showed that the left side of the tongue was extremely thickened—nearly three inches thick—and that the right side was very little affected. Cracked ice was immediately applied to that portion of the tongue that could be reached. Diagnosis: Left hemiglossitis. The sublingual veins were opened as soon as a knife could be procured, some fifteen minutes later. The patient could articulate (very thickly) immediately after the blood began to flow, and his mental condition improved at once. Ice was ordered now for external application, as the left cheek and left side of the neck were beginning to swell rapidly. An hour later more blood was drawn from under the left side of the tongue, with relief (for the patient had again become unable to articulate. The bleeding was repeated each hour thereafter until about noon, after which the swelling did not again increase on that side of the tongue, but began on the right side and rapidly increased, so as to make articulation again very difficult. The same treatment was applied on the right side of the tongue that had been given to the left, and in the mean while three leeches were applied to the lower angle of the left jaw. At 1 P.M. the pulse was 108; temperature, 101° F.; respiration 18 and pretty full. The leeches were still on the left side, and the right side of the face and right side of the neck were swelling but under control by blood-letting from the under surface of the tongue. Here a different course had to be adopted in bleeding, for the veins could be seen, there having been so much rolling over of the tongue to the right side, and longitudinal cuts were therefore made as near the under side as possible. The bleeding was at first not very free, but a little later the veins were reached and the improvement was as rapid as it had

⁶ Zeitschr. für Heilkunde, 1880-81, p. 417.

⁷ Deutsches Archiv f. klin. Med., ii., p. 1, 1892.

been on the left side. A catheter was left with the nurse, with instructions how to use it in case of œdema glottidis. Solution of acetanilid in fifteen-drop doses, about one grain, was given every hour. Swelling of the right side of the tongue began to go down rapidly about 2 P.M., but the glands of the neck on that side remained swollen.

The mouth was now douched with ice water, as patient could control the water from going down the throat. This was continued for ten minutes and repeated each hour. Mustard leaves were applied to the feet and removed when these became very red. Hot applications to the abdomen were also made.

The subsequent incisions in the tongue showed white lines of tenacious pseudo-membrane (the knife and hands were thoroughly aseptic). The mouth was sprayed every hour with a solution of the permanganate of potassium. Patient left the city on December 10th and has not been heard from since.

The case presents some peculiar features. No cause could be found for the glossitis—there were no sharp edges of any of the teeth. The patient had never had syphilis and no other known poison had been absorbed or injected; recovery took place without the formation of pus. The case is reported as interesting because of these features and the probability, so far as can be seen, of the glossitis being the direct result of cold, as is claimed by some authors, among whom Cohen, in "Pepper's System of Medicine," may be quoted.

One other feature deserves mention—the fact that first one side of the tongue only was affected and then the other, and to this may be attributed the further fact that there was no protrusion of the tongue, as is usually the case, but rather a rolling over and pointing downward of the tip, which was caught behind the lower teeth and during the time it was swollen could not be dislodged from that position, except partially.

BILATERAL ORCHIDECTOMY, SUPRAPUBIC CYSTOTOMY, FOLLOWED BY ACUTE MANIA AND DEATH.

By WILLIAM WARREN TOWNSEND, M.D.,

RUTLAND, VT.,

GENITO-URINARY SURGEON, VERMONT STATE HOUSE OF CORRECTION.

REALIZING that the advisability of bilateral orchidectomy for prostatic hypertrophy is still under discussion, and believing that it is the duty of every operator to give a full and detailed history of cases that come under his observation, I report the following:

S. M. P.—, aged sixty-seven, farmer, came to consult me in regard to a bladder trouble which he had had for the past five years, and gave the following history: Up to the beginning of his trouble he had always enjoyed good health, and had been a hard worker. He was always very energetic sexually. He gave a complete history of beginning prostatic hypertrophy, namely, frequent and nocturnal micturition, lack of force to stream, etc. The use of the catheter began two years before, as voluntary micturition had become impossible, and since then he had consulted a number of physicians, who advised various internal remedies, vesical irrigations, and suppositories. Since using the catheter he had been growing worse; introduction of the instrument was getting more painful, and had to be performed every hour, day and night.

The urine contained a large quantity of pus and some blood. The prostate was enlarged to about the size of a goose egg. The passage of a searcher through the prostatic urethra excited a severe paroxysm. The bladder contained 55 c.c. of residual urine which was ammoniacal. Stone was suspected but was

not made out by the examination, as this was quite painful and the patient would not consent to an anæsthetic merely for an examination. Cystoscopy was not performed for the same reason. As the case seemed to me to be an ideal one for bilateral orchidectomy, and as the patient was in excellent condition in other respects, I advised operation, which was assented to. November 3, 1895, I performed the operation in the presence of a number of my associates. The first forty-eight hours after operation the patient was in excellent spirits, and other than pain from the wound and that occasioned by catheterization, which was performed every two or three hours instead of every hour, as had been done previous to operation, he suffered little. On the third day the dressings were removed and the wound was found to be healed. A collodion and gauze dressing was put on and from the time of operation up to the fifth day all went well. Catheterization was performed every two or three hours and frequently when the beak passed the cut-off muscle urine would flow out along side the catheter.

Beginning about the fifth day the patient, after the bladder had been voided of its contents, experienced severe pain near where the beak passed into the prostatic urethra, and after the bladder had been voided of its contents.

Examination of the prostate by palpation per rectum showed that there had been atrophy. In passing the catheter I detected a distinct grating on withdrawing the instrument, and with the searcher and various manipulations vesical calculus was made out. Operation was advised and one week from the day of orchidectomy I did a suprapubic cystotomy, and removed three calculi weighing in all forty-eight grams. The patient recovered from the shock of the operation and on the day following was doing well; the urine was draining from the bladder and his condition was good.

The second day following the operation the temperature ran up to 102° F., whereupon the gauze packing was removed, the bladder washed out, and a drainage tube inserted; the temperature came down to 101° F. following the dressing. Pulse and respiration were of good character up to within a few hours of death. The next morning he had a normal temperature, but was somewhat delirious. Thinking that there might be some septic condition, I removed the tube, irrigated, and repacked with gauze. He grew more delirious, was very restless, and insisted upon getting out of bed. Bromides and sulphonal failed to quiet him, and on the following morning I found him in a maniacal condition and requiring the services of several attendants to keep him in bed. I called Dr. L. C. Stillings in consultation, who advised hypodermatic injections of hyoscine and feeding with the œsophageal tube introduced through the nares (as the patient refused nourishment, thinking that we were trying to poison him). This form of treatment was carried out until death took place from exhaustion, eight days after the suprapubic operation and fifteen days after the bilateral orchidectomy.

What caused this maniacal condition? We can certainly eliminate the idea of sepsis, as the wound was perfect in each operation, and so far as uræmia is concerned I think that also can be eliminated, because a very careful examination, both microscopical and chemical, was made of the urine and no sign of kidney lesion was discovered. Was it possible for the mental condition to be due to the severe strain in undergoing two such serious operations in so short a time when recovery or rather alleviation from the painful symptoms was anticipated as a result of the orchidectomy? This we might expect in an hysterical subject, but hardly in the patient in question.

In reviewing the literature, I find a quotation from the *British Medical Journal*, May 18, 1895: "The author reports seven cases in which this operation was performed and in the first hemiplegia occurred, with death four weeks after the operation. The second developed signs of acute mania six days after the operation and died ten days after; the third also developed mania and died on the twelfth day; the fourth exhibited the same symptoms with the same result, death. The fifth had no appreciable mitigation of the urinary trouble thirty days later. The sixth was one of single orchidectomy, but the patient died in a few days in a state of mental aberration; and finally the seventh, also a single orchidectomy, developed distinct mental weakness, and death followed."

It is well known that when oöphorectomy was first being done, numerous cases of mania were reported following the same. Should the testicle and brain not maintain the same relation to each other as the ovary and brain? I will leave this to the neurologists.

In conclusion I will say that as for the operation relieving the prostatic hypertrophy it was a success, as there was a marked decrease in the size of the gland, determined not only by rectal palpation but by palpation and ocular demonstration through the suprapubic incision. Although unfortunate in not being able to report a favorable case, I will operate again, as the favorable cases that have been reported outnumber the unfavorable ones. In the case just reported the prostate did decrease in size and I have every reason to believe that, had the patient lived, the prostate would have been reduced so as to have allowed the urine to be voided voluntarily *per vias naturales*.

NARCOTINE IN MALARIA.

By LOUIS C. AGER, M.D.,

ASSISTANT BACTERIOLOGIST TO THE HOAGLAND LABORATORY, BROOKLYN.

IN the MEDICAL RECORD for September 21, 1895, the statement was made that the opium alkaloid "narcotine" or "anarcotine" was being used very successfully in India as a substitute for quinine. The drug was recommended in the acute forms of malaria only, but it occurred to me that it might be useful in hemicrania, supraorbital neuralgia, and the other chronic forms of malarial poisoning that are often so difficult to deal with. After considerable difficulty I got some of the drug from a wholesale house in New York and put it up myself in two-grain capsules. The first case in which I used it was that of a woman about thirty-five years old. She had had acute malarial fever a few years before and had been troubled with neuralgia in various forms ever since. About a month before I saw her she had a severe attack of hemicrania, which had only been controlled by the hypodermic use of morphine. When I saw her she was suffering from a similar attack of a severe character. I gave her three two-grain doses of narcotine half an hour apart, then two grains every four hours, till about fourteen grains had been taken. The patient was much relieved after the third dose, and has had little or no return of the trouble in the last three months.

Since that time I have used narcotine in a few similar cases with very good results. In one case there was considerable heart depression about two hours after the third dose, but not so much as sometimes occurs after full doses of the coal-tar analgesics.

Although my experience with the drug has been far too limited to furnish any positive knowledge of its usefulness, I feel encouraged to try it further and to suggest it to others.

Surgical Suggestions.

The Hot Iron.—Before using it render the skin area anæsthetic by applying pure synthetic crystallized guaiacol, in quantity of from twenty to sixty drops. —PIZE.

Epitheliomata of slight extent often give way to such mild means as the following solution frequently applied:

R Resorcin	2 gm.
Potass. chlorat.....	10 "
Aq. dest.....	300 "

—BROCK.

Burns of the Second Degree.—

R Carbonate of lime	10 gm.
Oxide of zinc	5 "
Starch,	
Linseed oil,	
Lime water.....	āā 10 "
Ichthylol.....	1-3 "

M.

—LEISTIKOW.

Orchitis.—Apply a few drops of guaiacol over the scrotum.—BALZER.

Analgesia, without irritation of the skin, is best obtained by adding an equal part of glycerin, or some vehicle which can be absorbed by the skin, to guaiacol, and covering with tissue to prevent evaporation.—FERRAND.

Tedious Labor.—After a case of tedious labor, an iodoform pessary is to be inserted in the vagina. A similar pessary is to be used night and morning for the first three days, and once in twenty-four hours for the next six days.—*Clifton Dispensary Rules for Midwives*.

Dr. Cheever, in the *Boston Medical and Surgical Journal*, says it is not advisable to operate in glandular infiltrations so extensive as to preclude entire removal; neither is it wise to operate when you cannot remove the whole disease, as in a tuberculous organ of which you excise a part, nor in a sarcoma of the antrum in which you cannot extirpate the sphenoid cells. It is allowable to depart from these rules when the pain is so agonizing that unless the suffering can be palliated the patient had better die than live; and also in a "forlorn hope," so-called, the patient is entitled to an operation if he assumes the responsibility. Even then it is well not to operate unless there is some slight chance of success.

Deaths from Anæsthetics.—The German Surgical Society gives the following statistics for the past five years in regard to mortality from anæsthesia: Chloroform was administered 201,224 times, with 88 deaths, or in the ratio of 1 in 2,286; ether, 42,141 times, with 7 deaths, or in the ratio of 1 in 6,020; chloroform and ether, 10,162 times, with 1 death; chloroform, alcohol, and ether, 5,744, with 1 death; ethyl bromide, 8,967, with 2 deaths.

Spontaneous Straightening in Rickety Curves of the Legs.—Dr. Bruns concludes from observations in Tübingen (*Beiträge Chir.*, vol. xvi., 1) that the greatest number of cases undergoes spontaneous cure in from two to four years. If the curves are unchanged at the sixth year, spontaneous cure does not occur. The chief aim of treatment should be to improve the general health. Of the number of cases under observation 75 per cent. were cured, 15.3 per cent. were improved, 9.7 per cent. remained unchanged. He considers that after the acute stage it is not harmful for children to be on their feet.

Epididymitis.—The testicle should be wrapped in lint and moistened frequently with lead water and opium, or the following:

R Tincture of aconite,
Tincture of opium āā ʒi.
Dilute lead water,
Water.....āā ʒij.

Osteomyelitis.—Dr. Funkhouser, of St. Louis, says the chief diagnostic point in osteomyelitis is the acutely sensitive spot near the junction of the epiphyses.

Fistula in Ano.—Dr. Gibbs, in the *New York Medical Journal*, March 21st, gives two reasons for failure in treating this trouble. 1. We are by no means sure of starting with an aseptic wound, though it is a simple matter to lay open a small, superficial, straight tract, and after thorough cleansing obtain immediate union. It is a different matter with an old fistula running under the skin and up around the intestine, with pockets and ramifications difficult to find, and all surrounded with thickened, new-formed connective tissue. In the latter condition, 2, the difficulty of preserving aseptic conditions long enough to allow of firm union in an organ which has to be functionally active, and at the same time is eliminating septic material.

Floating Bodies in Joints.—Dr. Halstead (*Annals of Surgery*, September, 1895) draws the following conclusions: 1. That the etiology of some of these bodies is not fully understood, but that the condition described by König under the name of osteochondritis desiccans explains most that are found in otherwise healthy joints. 2. Few are the direct result of violence. 3. The most pronounced symptom is severe pain in the joint, with locking of the joint, usually in a nearly extended position, this being followed by acute inflammatory processes. 4. The lengthening of the femur when there are movable bodies in the knee may be the result of irritation produced by the pressure of these bodies. 5. The only treatment is the removal by direct incision, preferably using cocaine anæsthesia.

Hypertrophy of the Prostate.—Where objection is made to castration, remove a small portion of the vasa deferentia and atrophy will follow. It may be done under local anæsthesia. Castration has given eighty per cent. of cures.—WHITE.

Abortion.—Dr. Jacob (*Monatschr. f. Geburtsh. u. Gynäk.*, September, 1895) thinks the right treatment is rest and opium, with extract of viburnum prunifolium. If there is free flooding with the os closed, the vagina should be plugged with iodoform gauze or aseptic wool. If the os is dilated to allow passage of finger, the ovum should be detached and extracted and the uterus syringed out once for all with any suitable disinfectant solution. When dilatation of the os is imperfect and flooding grows severe, it is right to press the finger forcibly through with great care and then effect extraction. In many cases the expulsion of the ovum may be left to nature. Ergot should be given for a week after abortion. Jacob deprecates the employment of the curette and vaginal irrigation.

Septic Peritonitis.—Dr. Brown concludes: 1. That septic peritonitis is a surgical condition, and should at the earliest possible moment be put under surgical supervision. 2. That all cases of acute diffuse peritonitis are not necessarily fatal, and while the mortality following operation must be great, many of these cases can be cured by prompt resort to the knife. 3. That success in these cases will depend on: (a) early operation; (b) careful cleansing of the abdominal cavity by sponging and irrigation; (c) by drainage by means

of glass drain, supplemented if necessary by gauze. 4. That all such cases should be operated on. No surgeon should fail to give his patient the benefit of the chance afforded by operation, no matter how desperate the condition may be: they all die without operation and many desperate cases are cured by prompt surgical interference.—*Medical Mirror*, May, 1896.

Tinea Tonsurans.—Dr. Harvey thinks that much of the scalp trouble found in institutions is due to the careless and too frequent use of hair-clippers. Girls with long hair seldom have ringworm of the scalp.

Dog-Tail Sutures.—It is said that the tendons found in the tail of a dog make better sutures than either catgut or kangaroo tendon, when properly prepared in sublimate.—*Peoria Medical Journal*.

Preservation of the Perineum.—Dr. Oliver, before the Ontario Medical Association, June, 1896, says that his method, when the perineum was rigid, was to introduce two fingers of the right hand into the vagina, and with each pain stretch the perineum in advance of the head. When full expansion is complete two fingers are introduced behind the occiput, and this part of the head is brought well down under the pubic arch. This, he claimed, should be a routine practice. He also advocated the method of expelling the head in the interval between pains by means of the thumb or finger in the rectum.

Local Anæsthetics.—Dr. Loup (*Bulletin Médical*, 1896) says that when a fluid is injected under the skin the nerve filaments are rendered insensible by driving away the blood and temporarily preventing its return, producing an anæmia. Dr. Loup, acting on this principle, has succeeded in producing an anæsthetic area by means of a perfectly neutral substance—sterilized olive oil.

Shall We Operate for Simple Fracture of the Cranial Vault?—Dr. Nancrede replies: "Bearing in mind the immediate risks of encephalitis and the future ones of epilepsy and insanity, there can be but one opinion as to the advisability of operating for all varieties of accessible fractures. An exploratory incision made with strict antiseptic precautions will resolve any doubt in cases of head injury, and if no bone lesion be found will heal promptly, adding nothing to the risks."

Ruptured Urethra.—Dr. Cabot (*Journal of Cutaneous and Genito-Urinary Diseases*, July, 1896) says: 1. In every case of ruptured urethra, immediate perineal section, with suture of the urethra, should be practised. 2. By this procedure not only do we greatly lessen the danger of urine infiltration and abscess, but we also, in a large proportion of cases, may hope to prevent the formation of close, intractable strictures. 3. In the early operation the search for the posterior end of the urethra is much easier than in the later. The hemorrhage from the branch of the artery of the bulb serves as a guide to that end of the canal.

Fibroids.—Dr. Martin says the indications for vaginal hysterectomy proper for fibroids must of necessity include only the smallest tumors, or, at best, fibroid uteri with long slender subperitoneal projections. The operation is often the ideal method of treating small multiple fibroids, which are so frequently the cause of severe uterine pains and excessive hemorrhage. Fibroids of considerable size may be treated by vaginal hysterectomy, when the uterus is low in the pelvis and the vagina is large and the tissues are loose. It is easy to turn a vaginal hysterectomy for fibroids into a morcellement if it be necessary.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

ELECTION OF COUNCILLORS OF COLLEGE OF SURGEONS—EXHIBITS IN THE HUNTERIAN MUSEUM—RUMORS ABOUT THE BRITISH MEDICAL ASSOCIATION—UNIVERSITY OF LONDON IN THE LORDS—HOSPITAL MANAGEMENT QUESTION—EDINBURGH INFIRMARY—GLOUCESTER EPIDEMIC—TESTIMONIALS—THE LATE DR. RALFE.

LONDON, July 10, 1896.

THE election at the Royal College of Surgeons has terminated in a way rather disappointing to the reformers. Mr. Bryant, Mr. Davies-Colley, and Mr. Pick were elected. There was no excitement whatever at the college, partly due, no doubt, to the large number of voting-papers which were employed, rendering it unnecessary for the voter to appear in person. Mr. Davies-Colley supplanted, so to say, Mr. Cadge, who usually voted in favor of reforms; so that the fight to secure them will be more arduous, and this election will be looked back upon as a decided check. It is not, perhaps, of much consequence, but the fellows seem determined to stick to all their privileges and deny the members any share in the government of their own college.

From July 1st to 4th there was, as usual, an exhibition of the additions made to the Hunterian Museum during the past year. They were placed in the council room of the college and examined with considerable interest. There is a very fine specimen of the gigantic extinct bird, moa, of the New Zealand South Island. The bones, I heard, did not all belong to one bird, but they have been very carefully selected to match, and some which could not be obtained have been supplied by accurate casts. It was said, too, that this skeleton is particularly valuable, as it contains both great toes and both coraco-scapulæ, as neither of these are to be seen in a specimen in the British Museum. A collection of cystic and other tumors originating about the kidney attracted some attention, as did a skeleton showing the changes of osteitis deformans. The dissected legs and feet from a case of congenital abscess of the tibia were also shown, as well as other interesting specimens.

It is whispered that there may be a little diversion at the annual meeting of the British Medical Association. I may say it is more than a whisper, to judge from a letter which is circulated in some quarters, threatening an attack on the *Journal* and its editor, to be led by Mr. Lawson Tait. He will probably be supported by a not inconsiderable number of members, provided the managers will give any chance for discussion; but perhaps they will once more adopt their usual plan of averting criticism or any unpleasant remarks by staving off this subject until close upon the announcement of refreshments or some equal attraction. They may, however, try this game once too often. Then it is said that probably the editor's health may not permit him to put in an appearance, when there would, of course, be no fight, but the usual loud and emphatic pronouncement by councillor after councillor of that mighty formula—"Our Great Association."

There are many malcontents among the would-be contributors of papers, especially to the ethical section. Among these is Mr. Laffan, of Castel, who has spoken out boldly and told his grievance, which is that the managers plead overcrowding as an excuse for rejecting his paper. He appealed to Mr. Tait, whom he seems to have imagined was a *persona grata*—an

error difficult to account for: and he declares that both *Journal* and association are in the hands of a clique—a statement which some think shows him to be a veritable Rip Van Winkle.

A bill for reconstructing the University of London has been introduced in the House of Lords. It adopts the recommendations of the Royal Commission, but in the present state of public business it has no chance of passing this session.

The question of management of hospitals, to which I have formerly referred, has caused some trouble in Edinburgh. Last winter one of the staff of the infirmary, who had been nominated by the College of Surgeons, resigned in order to gain extension of service in the wards, for, although there was no rule on the subject, the managers did not consider that any of the staff should be members of their board, and a new rule has been adopted to this effect. This arrangement is logical enough, as the members of the staff are in a sense the servants of the board; or, to put it more agreeably, officers appointed by and responsible to the board. As I have informed you, at some hospitals one or more of the staff have seats at the board, and in a few all of the staff are admitted, but in the latter case usually without votes. On a small board it is easy to imagine that the staff might virtually obtain the full control of the institution—a position which the lay members are not often willing to accept. Some representation of the staff must often be felt necessary. Perhaps the best plan is for the staff to hold separate meetings as a medical committee and communicate their resolutions to the board of management.

The epidemic at Gloucester is not yet over, although more than two thousand persons have been attacked. Last week there seems to have been some recrudescence. During the last six weeks the cases of small-pox notified numbered sixteen, twenty-five, fifty-six, forty-two, forty-seven, and eighty-four respectively. And yet the opposition to vaccination still continues, though on a smaller scale than before.

It is proposed at St. Mary's Hospital to get up a testimonial to Sir William Broadbent, and some would like to extend the subscriptions over a wider area. I scarcely know why, unless because he has obtained a baronetcy. It is true he has done his work well at the hospital, but he has had his reward and enjoys a large practice. There are so many calls to help poor doctors that I think the rich ones should decline to accept gifts from their brethren.

I regret to report the death of Dr. Ralfe, who a short time ago retired from the physiciancy of the London Hospital and was appointed consulting physician. He was a hard-working and exceedingly able man, and his retirement was caused by failing health. Your readers will know his book on "Diseases of the Kidney," which was perhaps his most important work. But his great knowledge of chemistry in relation to physiology and pathology enabled him to add to medical literature papers of permanent value on those subjects, and to give his students accurate and authoritative instruction. The profession loses in him an industrious and learned exponent of advanced medicine and a genial, upright colleague.

Resection of the Hip for Coxalgia.—1. Conservative treatment must be reserved for the first stage of coxalgia. 2. Surgical intervention in tuberculosis of the hip-joint is indicated as soon as pus has formed in the articulation. 3. In coxalgia without suppuration surgical intervention is indicated if the pain or the deformity resists continuous extension.—LAMBATTE, *Journal de Médecine de Chirurgie et de Pharmacologie*, 1895, t. iv., f. 3.

BERI-BERI TWELVE THOUSAND FEET ABOVE SEA LEVEL.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Professor Miura reports a case of beri-beri on top of Fujiyama in the month of December (*Sei-I-Kwa Medical Journal*, June, 1896), which is rather a staggerer. The temperature at that altitude is very low and the velocity of wind great. It is well known that beri-beri in Japan is a disease of June, July, and August, between the spring and fall monsoons, in an average temperature of 24.1° C. When the cool northwest monsoon comes in, beri-beri ceases altogether, even on the plains.

Now, if the disease were due to a germ, could it develop on Fujiyama when it does not in the plain? If it is due, as Professor Miura claims in this case, to insufficient alimentation and constipation, why should not this same cause operate elsewhere? Perhaps such a cold and snowy climate as such a mountain must have in the month of December caused the patient to use in excess the ordinary mode of heating of the Japanese, that is, the charcoal hibachi.

An individual on the top of Fujiyama in December must seek continued shelter—on the east side of the mountain, in an unventilated hut, anchored in some crannied nook, or in a cave—to escape the perpetual snowfall and bitter cold northwest winds. In such a place of refuge, carbonic fumes could accumulate.

All roads lead to Rome, and it seems to me that wherever I catch hold of a case of beri-beri I always somehow discover the carbonic gases.

ALBERT S. ASHMEAD, M.D.

NEW YORK.

"GERMS AND SERUMS."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the issue of the MEDICAL RECORD of July 18th, Dr. Lincoln Phillips attacks antitoxin in particular and the serum therapy and germ theory in general. To use his own words, "after reading his letter I cannot refrain from writing a few words in reply."

I agree with the doctor, that if we allow it we may be made the dupes of some of the chemical manufacturing companies; but, fortunately for us, we do not have to prescribe, *volens volens*, every preparation we see advertised, or even endorsed by any great gun of the profession; so the first paragraph of his letter is not, strictly speaking, the issue. More especially is this the case, as neither the germ theory nor serum therapy originated in the shop of any chemical company, but through patient and thorough work by conscientious investigators, who, most likely, never received any monetary return for their labor.

Dr. Phillips says: "What of antitoxin? Time will demonstrate, as it has almost done already, that it is a delusion and a snare." This is dogmatic, and I for one disagree with the writer. Up to the last few weeks I have been living in a locality where diphtheria is almost unknown—high up in the Alleghany Mountains in Virginia—and I have not had a case of true diphtheria in my practice since antitoxin made its appearance on the field; therefore I claim to be entirely disinterested and unbiassed. I have read and studied the subject, weighing each article pro and con., and my reading has not been with any preformed opinion in favor of antitoxin, rather the reverse: and I have come to the conclusion that in antitoxin we have a remedy which surpasses any other in its curative value in diphtheria. It acts in the same manner that vaccine acts in small-pox, and proves the truth of

simile dissimile est rather than that *similia similibus curantur*.

"Beware of the diagnostic powers of a man who reports from fifty to one hundred consecutive cases of diphtheria cured without the loss of a single one, antitoxin or no antitoxin." To that I say, Amen.

So far as I am aware, infallible cure has never been claimed for antitoxin, but statistics, gathered with as much care as possible, have proved that a mortality of 12.3 per cent. of all cases treated with antitoxin is such an advance over a mortality of 20.8 per cent. without its use, that we cannot ignore its curative value, and to say that it is a delusion and a snare is misleading.

The old cry of the anti-antitoxinists is, Mistaken diagnosis and unreliability of figures. Why a physician should be more prone to make a false diagnosis of a case because he intends to pursue one course in treatment in preference to another, I cannot see. If I lass one case as diphtheria because I use antitoxin, and call another case presenting the same symptoms follicular tonsillitis because I employ other remedies, I am wilfully creating an erroneous impression in the minds of both the laity and the profession. I for one cannot think that the gentlemen who have been at such trouble to get figures would lend themselves to such deception. Reasoning on this basis, what can false diagnosis have to do with it? If we have a mortality of 20.8 per cent. against 12.3 per cent. under the same conditions of false diagnosis, is not the balance in favor of the treatment which gives the lesser death rate?

The same may apply to "mild cases." We all know that one epidemic of contagious disease may be very much more severe and fatal than another; but surely a method in treatment does not affect the character of the epidemic, since it can affect only the cases under treatment. If it does, then Dr. Phillips is arguing against himself, as we have the lesser death rate with antitoxin, according to statistics. And we must go by them, as we have nothing else to go by.

I know it may be said that if figures are correct all the epidemics of diphtheria treated with antitoxin showing a decreased mortality presented a mild type, and in the past two years diphtheria has not been such a malignant disease as heretofore. All I can say is, may it continue to decrease in severity, as I have no means of knowing what the severity of the disease may have been, except the word of the men who "see blue through blue glasses."

"We are too enthusiastic over germs and germ theories." Let us consider briefly what is the status of the germ at present. Literally speaking, a germ is the original source or cause. Medically speaking, it is the organism or protozoon which causes disease. We know that the germ exists, for we see it under the microscope. We know that it multiplies, for we plant an almost invisible amount on a suitable sterilized medium, and in twenty-four or forty-eight hours we have a large mass containing, nay, made up of, hundreds of thousands of the same kind of germs which we planted. We know that in some cases they have the power of locomotion, as we see them scudding across the microscopic field like fish in the sea. We know that they produce disease, because inoculations in lower animals produce pathological conditions, as evidenced by post-mortem examinations and death. We know they produce specific disease, as inoculations of Klebs-Loeffler bacilli produce diphtheritic deposits, inoculation of pneumococcus results in pneumonic symptoms, tubercle produces tuberculosis, and so on. What can there be in this to be too enthusiastic about? And this is as far as the germ theorists claim to go; when it comes to counteracting the effects of these bacteria, we enter into the domain of therapeutics. If

we have discovered in germs, bacteria, micrococci, bacilli, spirilla—call them what we will—the cause of disease, have we not made a glorious beginning and one that may lead to great results in cure? For the first principle in treatment is to get at the cause. Can we be too enthusiastic over the germ theory?

If we are too enthusiastic over germs, we have to go back twenty years and acknowledge our complete ignorance of the etiology of many diseases, and especially of the cause of contagion and infection, as the only way we can explain these phenomena is in the presence of these "overestimated" germs.

When I studied medicine the germ theory was in its infancy and bacteriology was not taught in this country, but investigation since then has proved conclusively to me that bacteria are not myths, but living, moving organisms, having the power to produce disease and dangerous to belittle and ignore.

Asepsis and antisepsis have proved of inestimable benefit to surgery. Why? By inhibiting the growth of pyogenic organisms; and here we have tangible results. So with antitoxin, we have results through the deteriorated activity and virulence in the special diphtheritic bacillus, brought about by the influence of the antitoxin in direct contact with this bacillus and neutralizing its power in the system.

Dr. Phillips closes his letter by saying: "So that if we give a remedy and the patient gets well, what definite reason have we for assuming the patient would not have recovered without medicine?" I am afraid the doctor is either a fatalist or a faith curist. I am glad to say that I, with many others in the profession, can say that I am convinced that remedies administered by me have been instrumental in saving and prolonging life, and I regret that any one practising our noble calling should consider it such a happy-go-lucky empiricism as the writer does.

I pray you to excuse such a dissertation on a well-nigh worn-out subject, and I hope the doctor will not take umbrage at anything I may have said here.

W. H. F. MILLEF, M.D.

BALTIMORE, MD.

New Instruments.

A CERVIX KNIFE FOR DENUDING IN TRACHELORRHAPHY.

By AUGUSTIN H. GOELET, M.D.,

NEW YORK.

THE accompanying cut illustrates a knife designed for facilitating the denudation of the lips of the cervix in the operation of trachelorrhaphy as described in the

MEDICAL RECORD of July 4th. It consists of a two-edged pointed blade set at an obtuse angle to a firm shaft and handle. It is made in two sizes. The cervix is transfixed beyond the angle of cicatricial tissue and the blade cuts as it is drawn downward, denuding one side at a single stroke. The denudation can be accomplished with this knife in one-half the time that is usually consumed when scissors are employed, and the surface left for coaptation is more even and regular.

Tuberculosis.....	120	98
Typhoid fever.....	20	7
Scarlet fever.....	44	5
Cerebro-spinal meningitis.....	5	5
Measles.....	115	6
Diphtheria.....	195	24
Small-pox.....	0	0

Medical Legislation in New York State by the Last Legislature.—The amendment of greatest interest to physicians, passed by the last legislature, was that to section 145 of the public health law, relating to admission to examination. This amendment provides that admission to examination for the degree of M.D. must be preceded by the study of medicine for four full school years of at least nine months each year, including four satisfactory courses of at least six months each in four different calendar years. Under the law as it was the length of a school year was not stipulated and the former courses in medical colleges in this State averaged from five to seven months. The law further provides that New York medical schools and New York medical students shall not be discriminated against by the registration of any medical school out of the State whose minimum graduation standard is less than that fixed for the New York State schools. Another provision allows medical schools to matriculate conditionally a student deficient in not more than one year's academic work or twelve counts of the preliminary education required, provided the name and deficiency of each student so matriculated be filed with the regents' office within three months and that the deficiency be made up before the student begins the second annual medical course counted toward the degree. Students who had matriculated in a New York medical school before June 5, 1890, and students who had matriculated in a New York medical school before May 13, 1895, as having entered before June 5, 1890 on the prescribed three years' study of medicine, shall be exempt from the preliminary education requirement. It was further provided that a medical student certificate may be earned without notice to the regents of the conditioned matriculation either before the student begins the second annual medical course counted toward the degree or two years before the date of the degree for matriculants in any registered medical school, in the four cases following: (1) For matriculants prior to May 9, 1893, for any twenty counts, allowing ten for the preliminaries, not including reading and writing; (2) for matriculants prior to May 13, 1895, for arithmetic, elementary English, geography, spelling, United States history, English composition, and physics, or any fifty counts, allowing fourteen for the preliminaries; (3) for matriculants prior to January 1, 1896, for any twelve academic counts; (4) for matriculants prior to January 1, 1897, for any twenty-four academic counts. But all matriculants after January 1, 1897, must secure forty-eight academic counts, or their full equivalent, before beginning the first annual medical course counted toward the degree, unless admitted conditionally, as hereinbefore specified, when the deficiency must be made up before the student begins the second annual medical course counted toward the degree. This law took effect March 31, 1896, except

that the increase in the required course of medical study from three to four years does not take effect till January 1, 1898, and does not apply to students who matriculated before that date and received the degree of M.D. before January 1, 1902.

Two bills making changes in examinations failed to pass. The first provided that the regents shall not alone conduct preliminary examinations prior to applicants entering upon the study of medicine, but that colleges may also do it. The second provided that any citizen of the United States who shall have, after a regular course of study, received the degree of M.D. from a regularly incorporated medical college in the United States, in which the course of study is equal with the courses of study in medical schools in this State, and shall have practised medicine for at least three years, may, upon producing necessary proof of the above provisions, be licensed to practise medicine in this State upon the payment of a fee of \$25. A bill requiring the State board of medical examiners to issue a license to Abraham C. Miller, also failed.

Aside from the main amendment, noted above, the public health law was amended as follows: relative to dental examiners; allowing pharmacists who were eligible on May 24, 1894, to be licensed at any time; changing the qualifications for the practice of veterinary medicine; allowing the health officer of the port of New York to receive for fumigation and disinfection of every vessel from an infected port, or of such vessel as in his judgment shall require fumigation and disinfection by reason of exposure to infection or contagion, \$50, or such sum not more than \$50 or less than \$5, as may in his judgment be deemed reasonable, during a single quarantine; allowing the medical schools and colleges in the counties of Onondaga, Oswego, Madison, Cortland, and also Auburn State prison to have all unclaimed cadavers in those counties.

These amendments to the public health law did not pass: repealing the provision as to vaccination of school children; providing a fine of \$50, or imprisonment for six months, or both, for violations of regulations of local boards of health; providing that the town board of health shall be the village board of health in villages of under two thousand population; requiring a certain standard of test for lager beer, ale, and porter, and providing that lager beer shall be kept in storage for six months after it is brewed before it is sold.

A law was passed providing that every concern employing a master plumber in New York City shall register his name and address annually in March at the office of the department of buildings and receive a certificate of registration, providing he holds a certificate of competency from the plumbing board. Hereafter the plumbing and drainage of all buildings, both public and private, in the city of New York, shall be executed in accordance with the rules and regulations adopted by the superintendent of buildings. An appropriation of \$6,000 was made for equipping the quarantine boat *Ripple* with disinfecting apparatus. The health officer of the port of New York was given \$6,000 for expenses of maintenance and repairs on Fire Island, and for the salaries of the superintendent, watchmen, and other employees during the year 1896; and the regents of the university \$10,000 for conducting examinations in the preliminary education of dental students as required by the law of 1895, chapter 626, and of veterinary students as required by the law of 1895, chapter 860, and for deficiency in the general examination appropriation caused by increase in number of schools and students.

Efforts were made, without success, to exempt from jury duty veterinary surgeons and registered dentists; also to amend the code of civil procedure as to physi-

cal examination of plaintiff by physicians of the same sex; also to regulate the employment of medical expert testimony in criminal proceedings; also, providing that the term funeral expenses, whenever the same is used in connection with the settlement of the estates of decedents, shall hereafter be deemed to include the reasonable compensation of physicians and surgeons for services and medicines furnished to the decedent during the last illness in the lifetime of the decedent. An appropriation of \$3,500 was made for the State medical library.

A law was passed, making it a misdemeanor if any person in charge of an ambulance or hospital shall refuse in answer to a call for an ambulance to take to the hospital from which the ambulance came, for examination and treatment, the person or persons for whom a call may be made. A charter was given to the Merchant Marine Hospital Service, with William T. Jenkins, M.D., Carter S. Cole, M.D., A. T. Talmadge, M.D., C. W. Hogan, and Cornelius Van Cott as the incorporators. The commissioners of the sinking fund of New York City were authorized to lease to the Hospital for Scarlet Fever and Diphtheria Patients a piece of ground belonging to the city and situated on the block bounded by Avenue C, East River, Sixteenth and Seventeenth Streets. The board of trustees of Faxon Hospital in Utica were required to grant equal rights and privileges to practitioners of all schools of medicine.

The New York Homœopathic College and Hospital was allowed to charge for board, nursing, and medical or surgical aid and attention, \$1 a day for each needy and charity patient who occupies a bed in the Flower Surgical Hospital, belonging to the New York Homœopathic College and Hospital, such payment not to exceed \$1,200 a year. Another law confirmed the title of St. Luke's Hospital to certain lands in New York City by consenting to, ratifying, validating, and confirming certain deeds made by the mayor, aldermen, and commonalty of New York City, and certain deeds made by the rector, churchwardens, and vestrymen of the Anglo-American Free Church of Saint George the Martyr. Houses or homes for the reformation, protection, or shelter of females day nurseries or corporations or societies for the care and instruction of poor babies and needy children, and industrial homes and any benevolent or charitable corporation owning or maintaining public baths, for free school societies, or free circulating libraries, now existing in New York City, were exempted from the payment of water rates, under the law of 1887, providing hospitals, orphan asylums, and other charitable institutions in the city with water, and remitting assessments therefor. An appropriation of \$6,000 was made to the Pasteur Institute of New York City, as a full equivalent for services, as provided in chapter 770 of the laws of 1895. M. J. Dady was given \$4,500 to purchase the building and land situated at and adjoining the Kings County farm for the use of the hospital, valuation to be fixed by the board of managers of the hospital.

These hospital bills failed: legalizing certain acts of the board of supervisors of Erie County, and providing for the management and maintenance of Erie County Hospital as an institution separate from the almshouse: amending the town law so as to enable towns to raise money for the support of hospitals; allowing New York City to appropriate \$10,000 annually to the community of Notre Dame de Bon Secours (Good Help) for its charitable uses and purposes, and to St. Mark's Hospital, for board, nursing, and medical or surgical aid and attendance, \$1 per day for each needy and charity patient who receives such care, support, and maintenance from said hospital, such payments not to exceed in the aggregate \$30,000 per annum; providing for the erection of a

hospital in Brooklyn for the use of the department of charities and corrections and under its supervision.

A bill abolishing all the coroners in the State, in obedience to the new constitution, and with the approval of the State medical and bar associations, was introduced but not passed. It did away with all coroners, post-mortem examiners, coroners' physicians, and coroners' jurors, and conferred upon the appellate divisions of the Supreme Court power to appoint their successors. The bill abolishing coroners' juries also failed. A two-year term was made for the coroners of New York County; and a four-year term for the coroners of Kings County. In the former county the coroners were allowed to appoint two assistant clerks, who shall keep the office open between the hours of 4 P.M. and 9 A.M., every day in the year, including Sundays and legal holidays, one at least of said clerks being in attendance during said hours; but an effort to raise the salaries of coroners' physicians from \$3,000 to \$5,000 failed.

A law was passed protecting the owners of bottles, boxes, siphons, tins, or kegs used in the sale of soda waters, mineral or aerated waters, porter, ale, beer, cider, ginger ale, milk, cream, small beer, lager beer, weiss beer, white beer, or other beverages, or medicines, medical preparations, perfumery, oils, compounds, or mixtures. The law relating to instructions as to the bad effects of alcoholic liquors was revised. The trustees of the Clifton Springs Sanitarium Company were authorized to issue \$150,000 in bonds and to mortgage the trust property to raise money to pay the cost of completing the new sanitarium building. The charter of the Inebriates' Home for Kings County was amended relating to the appointment of directors.

Among the bills that failed were these: providing for the medical treatment of persons who have been convicted of public intoxication; providing for the treatment of the disease of drunkenness; providing for the treatment and cure of inebriates and persons addicted to the excessive use of opium and other narcotics; prohibiting vivisection and dissection in the public schools; relating to proceedings for the commitment of the insane to State hospitals and other institutions; charter for the Optical Society of the State of New York for the purpose of improving and regulating the practice of dispensing and refracting opticians.

Laws local to New York City were passed: authorizing the sinking fund commissioners, whenever required to do so by the board of health, to set apart land on the south side of East Seventeenth Street between Avenue C and the East River, and adjacent to the hospitals now under the control and supervision of the board of health, for the construction thereon of a building as an ambulance station and vaccine laboratory; for the relief of the Mount Sinai Training School for Nurses, and legalizing its incorporation. These bills failed: amending the law regulating the sale of poisons so that the name of the substance or substances best known and used as the antidote for the article contained in the box, bottle, vessel, or paper shall be given; forbidding any but a registered pharmacist to expose or offer for sale at retail any medicine, medicinal preparation, or poison whatsoever; allowing an officer or employee who has served thirty years in the health department of New York City to draw upon the health department pension fund; amending the charter of the Deutsche Poliklinik; making further provision for the proper maintenance, care, and treatment of sick, infirm, and destitute persons in New York City under the jurisdiction and care of the commissioner of public charities.

An amendment was made to the law enabling the Kings County Pharmaceutical Society to establish a college of pharmacy in the city of Brooklyn. These

bills were lost: allowing the commissioner of police and excise in Brooklyn to appoint not to exceed seven surgeons, and all surgeons so appointed shall hold such office at the pleasure of the commissioner; creating a board of physicians and surgeons for the city of Brooklyn, defining the duties thereof, and abolishing all surgeons connected with any of the departments of said city, except the department of health; amending the Erie County midwifery law of 1885, so that the county judge shall appoint a board of examiners in midwifery to consist of nine members (each with a three-year term), who shall have been licensed to practise physics and surgery in this State, and who shall have been in active practice for at least five years.

An Old-Timer.—A correspondent in Chelsea, Mass., sends the following: "Some of us in these days of tablet triturates and ready-made syrups, elixirs, solutions, and what not, are rapidly becoming rusty in the gentle art of writing the prescription, especially the one of the shot-gun order. To show that even our State board of registration has not caused this to become a lost art in the old Bay State, I beg to submit the following, taken from the file of one of our city druggists who has filled it twice during the last month. The man had gleet and said this cured him:

"R Calsum hypophos.....	z iij.
Potas. hypophos.....	gr. xxv.

"M. Too teaspoonfuls in water one-half hour before meals."

Syphilis from an Insurance Point of View.—Dr. P. H. Maclaren, of Edinburgh, in considering this subject without reference to general mortality statistics, from which it is difficult to obtain accurate information, states that he is inclined to classify for insurance purposes all syphilitics under the three following groups: 1. If a man has been properly treated, the probabilities are that, provided he is of good constitution and habits, no complications will arise, and the expectation would be that he will go through life with scarcely more appreciable risk than one who has never had the disease. 2. If proposer has not undergone a sufficient course of treatment, and applies for insurance before the expiration of six years, the period at which the disease normally terminates, and yet is not suffering from any tertiary manifestations, and is otherwise satisfactory, the chances are that he may escape the malign form, but ten per cent. extra should be charged until the expiration of the six years, and the case then reconsidered. 3. When tertiary symptoms have developed, the proposal should be absolutely declined, because, while treatment may temporarily remove these, it cannot eradicate the tendency to recurrence; and clinical observation has shown that those so affected rarely live beyond a term of ten years, and often much less when palliative treatment is not carried out. While his personal experience is almost absolutely favorable regarding the prognosis of the cases included in Class 1, it is questionable when the cases are looked at, with the interests of the offices perfectly safeguarded, if they should not practically be treated in the same way as those in Class 2.—*Edinburgh Medical Journal*, March, 1896.

THE ANTITOXIN TREATMENT OF DIPHTHERIA IN THE KAISER AND KAISERIN FRIEDRICH CHILDREN'S HOSPITAL IN BERLIN, AND DR. WINTERS' OBSERVATIONS THEREON.

By ADOLF BAGINSKY, M.D.,

EXTRAORDINARY PROFESSOR OF THE DISEASES OF CHILDREN IN THE UNIVERSITY OF BERLIN AND DIRECTOR OF THE KAISER AND KAISERIN FRIEDRICH CHILDREN'S HOSPITAL.

THE erroneous statements of Dr. Joseph Winters, recently made in the *MEDICAL RECORD*, regarding the statistics of the antitoxin treatment for diphtheria in the Berlin hospital of which I have the honor to be the supervising physician, have compelled me to present certain facts to my American colleagues which may be of interest in the pending discussion of the real merits of the new remedy.

Dr. Winters offers the following so-called observations from the diphtheria division of the cases treated in the Poliklinik and Klinik:¹

"When I first visited the Empress Frederika Hospital while in Berlin, I was first invited to attend the Dispensary Clinic for diseases of children, which opportunity I availed myself of. Such care in the management of cases of slight illness I do not think can be seen anywhere else in the world. The waiting-room for children is under the charge of a trained nurse. Every child has its temperature, pulse, and respiration taken by the nurse and its clothing removed; it is then carefully wrapped and taken before the physician. There again you see the same minute, painstaking care in every case. Noticing this great care and that not in a single instance was the throat examined, I thought it strange. The doctor told me that the throat was not examined in this room, because the throat of every child was examined before being brought to this room, and if there was any affection of the throat the child was referred to the diphtheria polyclinic. A clinic for walking cases of diphtheria was a revelation to me. The next hour I visited the room where the diphtheria polyclinic is held, under the supervision of the same physician. Every child brought to the dispensary department of the Empress Frederika Hospital, if it presents any throat lesion, is placed in an isolation room of the hospital which they now have for these cases; it is immediately injected with antitoxin, and if Loeffler's bacillus is found, it is placed in the diphtheria pavilion and receives further serum treatment. It is in this way that the enormous number of cases, as compared with previous years, is taken into this hospital for serum treatment. When there is a lack of serum or when there is no serum, these walking cases of throat affection are not detained in the hospital, as it is not deemed safe to do so when they cannot be immunized and protected against their surroundings. It is this method of conducting the diphtheria department of the Empress Frederika Hospital which accounts for the reported low mortality and for the difference in mortality during periods when se-

rum is used and when it is not used. It was this very feature of the reports from the Empress Frederika Hospital which made the strong impression on Virchow. But Virchow had not studied the details; he accepted the percentage mortality without knowing how such percentages were obtained."

In this portion of Dr. Winters' paper there are so many false statements, perhaps based partly on faulty observations, that I find it necessary to preface these remarks with a plain description of our methods as they actually exist:

In the Poliklinik (Dispensary) of our hospital we have two distinct departments, viz., an infectious department and a non-infectious department.

In the non-infectious department children are treated in the dispensary as out-door cases or are admitted to the internal wards of the hospital as medical or surgical patients. The surgical wards are under the charge of Professor Gluck, and are restricted to the reception of patients who have no infectious disease.

In the infectious department only really infectious cases are treated, in so-called pavilions especially designed for this purpose, and only a few cases and convalescents are treated in the poliklinik or dispensary. For this purpose the infectious department has a number of wards (so-called "Ordinations-Zimmer"), and these are not, as Dr. Winters says, isolation rooms "which they now have for these cases," implying that they have been in existence only since the antitoxin treatment was introduced. This department has existed since the opening of the hospital in 1890. In other words, these isolation wards existed long before anybody thought of antitoxin. These wards are variously labelled: "For scarlatinal cases," "for diphtheria cases," "for pertussis cases," "for measles cases;" for surgical infectious cases, such as erysipelas, phlegmons, vulvo-vaginitis, blennorrhœa neonatorum; and, finally, we keep one room reserved for special purposes.

The division, or, rather, the distribution of the various new cases, is managed by one of my assistants, a physician especially named for the position. His work consists in examining the cases and sending them to their various rooms on the strength of the diagnosis made by him. Naturally, the throat is carefully examined and each symptom given proper weight. This physician, furthermore, examines the urine of the children, for it is here that we frequently observe those pathological conditions which are the forerunners of infections. Although every child is strictly isolated until we arrive at a proper diagnosis, it is the invariable rule in our wards to re-examine the throat of every child before treatment is commenced; so that it is untrue and improper for Dr. Winters to state that he recently observed anything different in spite of our "painstaking care." The throat of each and every case is not only examined by my assistants, but frequently by myself, and, as a rule, every important case is treated by me personally, and detained by the assistants if a doubtful diagnosis exists until I corroborate it or otherwise. It is to be taken for granted that I examine thoroughly all cases before giving my opinion.

To again quote Dr. Winters: "The throat was not

¹ *MEDICAL RECORD*, June 20, 1896.

examined in this room." This latter is absolutely untrue, and it is equally evident that Dr. Winters has misunderstood all our methods.

We could even overlook some of Dr. Winters' remarks, were it not for the fact that he distinctly states that a case of angina in a child "is immediately injected with antitoxin." This is such a glaring misstatement that I find it difficult to understand how and why Dr. Winters could be willing to permit such an assertion to appear in print.

In the special diphtheria room above mentioned all cases of spurious angina which simulate diphtheria are carefully examined, not, as Dr. Winters puts it, "by the same [admitting] physician," but by the special diphtheria assistant, one of my assistant physicians, who has charge of the diphtheria pavilion; and it is he who, as special assistant in this disease, is required by me to separate all cases of catarrhal angina from those of diphtheria. For this purpose this assistant of mine is required to use all necessary clinical, microscopical, and bacteriological methods in arriving at the proper diagnosis.

Children with apparent diphtheria are brought in the diphtheria pavilion. It is in this separate diphtheria building that antitoxin treatment is commenced, and not, as Dr. Winters erroneously puts it, "receives further serum treatment."

Other cases in which the diagnosis is not clear are disposed of in two ways: 1st. They are admitted to the quarantine, which is situated on the whole of the upper part of the poliklinik or dispensary building, and are subjected to careful scrutiny; or, 2d, they are given out-door treatment, consisting of gargles of chlorate of potassium, quinine, and ice compresses; but the mothers are invariably given strict instructions in regard to isolation, care, diet, and medication.

I should be pleased to have Dr. Winters inform me how he came to state that a child had been injected "immediately" with serum in our poliklinik or dispensary. The treatment with antitoxin is given only in the diphtheria ward or pavilion, in some cases in the quarantine station, but never otherwise.

But it is proper, also, to state when and why we have given injections "immediately" in our poliklinik. All the brothers and sisters of a patient with diphtheria whom we admit in our diphtheria pavilion receive "immunizing injections of antitoxin," when we are positive that a case of diphtheria really exists; and these injections are given soon after the antitoxin treatment is commenced in our poliklinik, and are for the purpose of conferring "immunity." And I would furthermore ask Dr. Winters to inform me "when and where" I called cases which were given immunizing injections of one hundred and fifty and two hundred antitoxin units "cases which were treated and cured," as though they had been ill with diphtheria. The observations as given by Dr. Winters and all his conclusions are incorrect, and are based on such faulty observations as to amount almost to misrepresentations.

It is absolutely untrue that at the time when no antitoxin could be procured children were sent away. Dr. Winters was in our hospital, according to our visitors' list, once only, and it is, therefore, quite evident that we cannot expect him to know our exact mode of procedure from one superficial inspection; for I repeat that our working methods are exactly now as they have been since the hospital was opened in 1890.

If, however, he had wished to be thoroughly informed about our working and scientific arrangements, he could have received such information in New York City from one of your physicians, Dr. Louis Fischer, who is thoroughly conversant with our *modus operandi*, and has had an abundant opportunity for acquainting himself with it. Besides, I believe he was one of the

first to introduce and generalize the antitoxin treatment in America after having learned it in our diphtheria wards.

Therefore, with such flimsy knowledge of our ways, all of the so-called observations and experience of Dr. Winters at the Kaiser and Kaiserin Friedrich Children's Hospital as regards the antitoxin treatment amount, *a priori*, to nothing.

Now, as regards my own experience and my views concerning the antitoxin treatment of diphtheria in the Kaiser and Kaiserin Friedrich Children's Hospital, I can only endorse every word that I have said or written in its favor, and will stand by it.

I regard it as useless always to go back to statistics and repeat them, for, by putting together a lot of figures one will never be able to convince people. In statistics there are so many things to consider, so many to discard, and so many facts to analyze that one cannot only prove every absurdity, but can often succeed in disproving facts.

I consider it of prime importance to classify each and every case according to (1) its primary or earliest clinical manifestations; (2) its course, and (3) its termination. Under these conditions I am in a position to announce some new facts:

1st. Our cases are to-day just as severe as they have ever been on admission to our hospital. It is absolutely untrue that since the introduction of the serum treatment we have been dealing with milder forms of diphtheria. On the contrary, we have had the worst forms and most malignant cases during all this time as well as during the last few months. It is therefore wrong to speak of mild epidemics, for even in my private consultation practice I have met the worst forms of diphtheria.

2d. In spite of the malignant type of our cases we find that the course of treatment since the introduction of the so-called healing serum is so much more favorable that a comparison with former methods is uncalled for. We can easily compare results of the former clinical methods by noting the percentage of mortality. As an example allow me to offer the following statistics of the first half of the present year:

1896.	January,	number discharged cured,	27;	died,	2 = 6.89%
	February,	"	"	25;	" 4 = 16%
	March,	"	"	25;	" 3 = 10.71%
	April,	"	"	25;	" 0 = 0%
	May,	"	"	25;	" 3 = 10.71%
	June,	"	"	20;	" 1 = 5%

This is the percentage of mortality which we can place opposite former percentages of forty to fifty per cent. But this would be hardly enough if we did not consider the course taken by convalescing cases and the remedy used in the treatment.

3d. When the antitoxin treatment was first introduced opposition was thought to be justified by the fact that with the greater number of admitted cases more mild cases were admitted to the hospital, and so it was asserted that a larger number of milder cases were treated to swell the favorable statistics. To disprove that I can show that, although the number of cases admitted has been considerably lessened and the cases taken were always of the severest kind, the mortality has diminished and the percentage of discharged cured has considerably increased.

4. I have as yet never noticed, after an injection of antitoxin, whether the remedy was employed as a curative agent or was used in prophylactic doses to confer immunity (excepting in two cases which I shall report in detail later), any symptoms which were detrimental to the health of the patient. In the large amount of carefully studied material, I have looked at every factor and watched for harmful results, and cannot find a single fact which would tend to destroy my confidence in the absolute value of this antitoxin as a

healing agent in diphtheria. I therefore cannot understand the reports of other observers about the poor results and effects of the serum. Surely it is not possible in comparison with the great value of antitoxin observed in such a large number of cases of diphtheria in our hospital to diminish this value by a few reports of unsuccessful or doubtful cases occurring elsewhere.

5th. It is highly important that in the treatment of diphtheria with antitoxin the physician should first ascertain the quality of the antitoxin used and not take the first substance he finds labelled in the market. For it is a well-known fact that some alleged antitoxins are absolutely inert. It is therefore advisable to use, as we are in the habit of using, antitoxin the preparation of which is under the control of the German government. We use in our hospital two kinds of antitoxin: 1st, Aronson's and, 2d, Behring's.

6th. It is also necessary to remember that diphtheria is a disease attended by many grave complications and that antitoxin is not our sole reliance in such emergencies. To be markedly successful in this disease the physician must be a pathologist and a therapist and be thoroughly in touch with all the special indications that may arise during its course. If he does not properly understand the leading principles of treatment the best remedy we have will be a failure with him. The results to which I refer have been achieved not only in the hospital, but also in private practice.

I do not intend to go any further into this subject at the present time, but think it just to give my American colleagues a proper insight into the true state of affairs as they exist here and the facts as gained from the material under observation.

It is to be sincerely hoped that should American observers desire to pass criticism on our methods or report the affairs of our hospital they will qualify themselves with better information and study our workings properly—not as Dr. Winters has done or believes he has done. I am always ready to offer my hand cheerfully for this purpose.

THE ANTISEPTIC TREATMENT OF TYPHOID FEVER.¹

BY WESLEY DAVIS, M.D.,

WORCESTER, MASS.

IN the time allowed me I can point out only in the most cursory manner some of the methods employed, with very little in the way of full illustration.

I wish first to direct your attention to the etiology of typhoid fever. I suppose we are all agreed and ready to admit that it is a germ disease; that the germs may enter the body by the way either of the air or of the food and drink, and that whichever way they enter they are carried through the œsophagus to the canal below, when they find a most favorable culture medium as they approach the lower portion of the ileum; then they multiply with great rapidity, all the conditions being favorable. The ptomains which they form are absorbed and cause the fever with which we have to contend; moreover, the germs themselves are taken up entire and carried through the glands and lymphatics to many tissues of the body, when, of course, they may continue with more or less activity their toxin-producing mission.

But nowhere are they found in such abundance, and nowhere are the conditions so favorable for their multiplication, as in the lower portion of the small intestine. This undoubtedly accounts for the greater fre-

quency of the typhoid lesions in this locality. The glands here take up from the contents of the intestine a greater number of bacilli than do the glands in other parts of the canal, simply because this is the most favorable culture ground, and consequently there are more bacilli and ptomains here to be absorbed, as well as more glands to be affected by their absorption.

It seems to me we must all admit that this fever is dependent upon the absorption of these poisonous ptomains into the blood, as is the case in diphtheria and septicæmia. We should look upon our patient and endeavor to judge by his condition as to the amount and severity of the poisoning taking place. In any other disease than typhoid fever we would endeavor to cleanse the source of infection with antiseptics, and the more thoroughly we were able to accomplish this the better would be the chance for recovery.

Now, as I view the matter, this is precisely the condition of the typhoid patient: the small intestines are the source of the trouble and the problem for us to solve is what we can do to overcome or prevent this poisoning from continuing. If we could stop it at once we might see as rapid cures as we sometimes do when septic conditions are removed from other parts of the body and we should have an aborted typhoid fever.

Since we cannot reach the site of infection, as is possible in many unclean surgical cases, the next best thing is to wash out the intestine with cathartics, which, if begun early enough and combined with suitable antiseptics and copious draughts of sterilized water, must carry out of the system multitudes of bacilli that otherwise would remain to multiply and generate their ptomains for continuous poisoning.

If this be true, it naturally follows that we must continue to flush out the canal with antiseptics just so long as the bacilli remain and develop the toxin which keeps up the fever. We have quite an extended list of antiseptics that have been tried and are claimed to be useful for this purpose, among which may be mentioned naphthol, naphthalin, thalline, salol, resorcin, sulpho-carbolate of zinc, and arsenite of copper.

I have unwittingly had a little experience with the zinc, the result of which has interested and I think instructed me greatly.

Last August I was called to attend a girl who had become so ill she could not continue her work longer as a domestic and was taken home by a cousin to be cared for. I found her with what seemed a very severe attack of cholera morbus, so severe that for a day or two I feared collapse. At my first visit I put her upon grain doses of sulpho-carbolate of zinc every hour in addition to the other treatment. About the fourth day, the choleraic condition being improved, she had a temperature of 104° F., and developed a parotitis which aroused my first suspicion of typhoid fever. I directed the nurse to disinfect the stools and be careful, but evidently too late. I saw this patient eight days, when she was so far recovered that I did not consider it necessary to put her in other hands when I left town. The week following the cousin was attacked with typhoid fever and was ill nine weeks, my patient becoming the nurse. Her husband came under my care at the City Hospital October 19th, having been sick two weeks, and was discharged November 16th. A boarder in the family, also having been sick two weeks, was admitted to the hospital September 9th and discharged October 14th. The men were ill six and seven weeks each and the woman nine.

Why did my patient recover so rapidly? Is it unreasonable to believe that the bacilli were eliminated

¹ Read before the Worcester District Medical Society, April 15, 1896.

by nature in spite of my efforts and that the sulphocarbonate of zinc acted as a disinfectant? Or shall we consider it as confirming Dr. Chambers' claim that the fever can be aborted early by emeto-catharsis?

My patient was actually ill not over two weeks, yet lost her hair as thoroughly as did her cousin, who was sick nine weeks.

At our annual meeting in May last I called attention to the Woodbridge treatment and showed the chart of a case then convalescing. The case made a rapid recovery, the result being so satisfactory that I have treated every case coming under my care since by the same method.

In the City Hospital we had eighteen undoubted cases of the fever during my service from October 1st to January. These cases all recovered, and those uncomplicated pursued what appeared to be an unusually mild course. It certainly seemed encouraging for the treatment when we found there were fifty-one cases reported to the Board of Health outside the hospital during this period, with twelve deaths, a mortality of 23.5 per cent. against none at the hospital, while during the same period of 1894 we lost four out of eighteen under the regular treatment.

I have treated eight cases in private practice, which have done well and served to strengthen my faith in the method.

Dr. Woodbridge has reported another series of fifty cases, making in all over four hundred, without a death among those uncomplicated. He also reports eight hundred cases reported by one hundred and seventeen other physicians, with nine deaths. He states that "seven certainly, and possibly eight of these were due to grave complications (developed prior to the commencement of the treatment) or to the late stage of the disease at which treatment was begun, or possibly to faults of preparing or administering the remedies."

So far as I have been able to learn from the journals, every one who has had faith and enthusiasm enough to carry out the treatment faithfully gives a favorable report.

We will now turn our attention to the treatment itself. Here are the formulæ:

TABLET NO. 1.

R Podophyllin	gr. $\frac{1}{10}$.
Calomel (hydr. chlor. mit.)	gr. $\frac{1}{15}$.
Guaiaicol carb.	gr. $\frac{1}{15}$.
Menthol.	gr. $\frac{1}{15}$.
Eucalyptol.	℥ i.

TABLET NO. 2.

R Podophyllin	gr. $\frac{1}{10}$.
Hydrargyri chloridi mitis	gr. $\frac{1}{15}$.
Guaiaicol carb.	gr. $\frac{1}{15}$.
Menthol.	gr. $\frac{1}{15}$.
Thymol	gr. $\frac{1}{15}$.
Eucalyptol.	℥ i.

NO. 3 CAPSULE.

R Guaiaicol carb.	gr. iij.
Thymol	gr. i.
Menthol.	gr. ss.
Eucalyptol.	℥ v.

You will observe the laxatives do not enter into the composition of the capsules.

In the use of these, No. 1 is to be given at once and thereafter every fifteen minutes for the first twenty-four hours, as directed by Dr. Woodbridge. I have given them thus, but on attempting to dissolve the tablets concluded they might as well be given at intervals of half an hour in double the dose, *i.e.*, two tablets every half-hour.

At the end of the first day if these are well borne, and the bowels have not moved too freely, two No. 2 tablets are to be given every hour alternately with two

No. 1 tablets, so that the medicine is given every half-hour.

If five or six free evacuations occur during the second twenty-four hours the treatment can be continued, or the intervals lengthened to three-quarters of an hour or more, according to the judgment of the physician. My experience is that patients do best when the bowels are kept well open.

After three days capsule No. 3 is given, one every three hours, between which the tablets, mostly No. 2, are given, according to the effect to be maintained upon the bowels. The ideal management of a case would be to have the frequency of the dejections diminish from six or eight, *pari passu* with the fall of temperature, until there should be only two or three in twenty-four hours when it reaches normal.

There is nothing in the treatment that contraindicates the use of baths, turpentine stupes, stimulants, tonics, or opiates to relieve pain, and I have always used them when indicated.

Realizing the impossibility of reproducing in the MEDICAL RECORD the thirty and more clinical charts exhibited when the paper was read before the society, I will give a brief history of some of the cases and draw a few conclusions which seem warranted from a study of all the charts:

April 14, 1895.—First saw Mr. C——, the case already referred to, who had a temperature of 104° F., severe pain in head and back, with general soreness. He was given acetanilid and quinine without relief. Bromides also failed and morphine was resorted to on the 16th, his bowels having been previously moved by calomel, ipecac, and soda, and showing no tendency to overact.

April 17th.—His head was still aching and he begged for relief, which was obtained by morphine, but the pain returned as soon as he awoke.

April 18th.—He continued much the same, with persistent fever and pain in head and back, which strengthened my suspicions of typhoid fever, and he was put upon the No. 1 tablets, one every fifteen minutes, the acetanilid being omitted. The following morning he had a temperature of 104.5° F., pulse 108. The tablets were then given every half-hour in double doses, as he objected to the frequency. This treatment was followed faithfully until he had eleven dejections during the second twenty-four hours, when the tablets were diminished in frequency and finally omitted. But for six days the number of dejections ranged from six to eight every day, when, becoming anxious as to their frequency, I ordered the milk scalded for a few days, and about this time the tablets and capsules were ordered made small as possible that they might be more easily taken. The characteristic eruption was well marked on the third day after the treatment was begun, and the next day, with a temperature of 104.3° F., he called for bread and milk, which was allowed whenever he desired. He had no delirium or tympany and the tongue was moist throughout.

Two days after he commenced on the small tablets and capsules his temperature was 100.5° F., but gradually rose to 102.8° F., when we discovered tablets in the stools. A visit to the druggist revealed the fact that he had combined the medicines with calcined magnesia in his efforts to make the tablets and capsules as small as possible, and this had rendered them insoluble.

We recovered in all over seventy-five tablets and capsules, and as soon as the medicines were made soluble his temperature dropped to normal in a night on the eighteenth day of the treatment. We would probably have reached a normal temperature several days earlier if the medicines had been soluble. His appetite was good and he indulged it quite freely and

made a very rapid recovery, going to Vermont on a business trip one month from the day the tablet treatment was commenced, and having had an evening temperature of 104° F. for over six days of the time.

If seventy-five and more of these undissolved tablets and capsules can pass through the alimentary canal of a typhoid patient and not produce a relapse, what have we to fear from the residuum of a beef-steak dinner, providing we keep the bowels open, well flushed out with an antiseptic solution? My experience has made me skeptical as to the influence of easily digested food in producing relapses.

In 1894 we had at the City Hospital three patients convalescing at the same time. One had passed the prescribed ten days of normal temperature and was put upon toast, which seeming to do no harm, he was given chicken after a day or two and the diet made a little more liberal, when after a day or two his temperature rose and he had a relapse, from which he ultimately recovered. The second had passed his period of normal temperature and was put upon toast only, when he relapsed but finally recovered. The third got a relapse the seventh day of normal temperature, having had no food, and died.

These cases impressed me strongly, as they occurred within a few days in the same ward and we could not ascertain any cause or learn that the patients had obtained any forbidden fruit or article of diet.

I am disposed to think relapses may be the result of late ulceration in Peyer's patches or the separation of sloughs in patches when ulceration has already occurred, thus liberating bacilli into the canal, which, occurring in connection with constipation, may give time for their multiplication and a reinfection of the system.

Here is a brief report of the last case treated, that of a lad of seventeen, member of the Classical High School. I saw him first the sixth day of the disease. Temperature, 102.5° F.; it reached 104° F. the eighth and again the thirteenth day of the disease. There is nothing especially interesting about the case except that he became so deaf after a few days that he could hear no ordinary conversation, and complained of a feeling of tightness as though a band were drawn about the forehead. He had no delirium, tympanites, or sordes; the tongue was clean and moist throughout all the latter half. He ate stale bread in his milk or broth whenever he desired, also chewed beefsteak, and usually drank two eggs a day beaten up in milk. He had an ice cap to the head, baths occasionally, but would not tolerate them cold. As he complained of considerable abdominal tenderness, turpentine stupes were applied. He had strychnine, but no alcoholic stimulants were used. A little opiate was given for a distress in the bowels that troubled him at times, and toward the last the cathartic effect of the tablets was assisted by one-third of a seidlitz powder each morning. His hearing returned as the fever subsided and he made a good recovery.

On July 27th I was called to a little girl, aged eight, who had been complaining for a week of pain in the head, back, and limbs. She had a temperature of 104.5° F. I put her at once upon one No. 1 every half-hour. The next day I found her so much improved that I thought I had made a mistake, the temperature being nearly normal. I omitted the tablets, but much to my annoyance two days later I found the temperature 103.5° F., when I put her upon tablets Nos. 1 and 2 alternately, three-quarters of an hour apart. I also ordered capsules of half-size, which she took without much difficulty. Her temperature reached normal August 4th, *i.e.*, in eight days, but treatment was not entirely omitted until nearly a week later. Her recovery was good.

George C—— had been feeling poorly for a week

or more, had consulted a physician twice, but continuing to grow worse, went to bed, where I found him. His temperature was not high, but the history and his condition impressed me with the feeling that I had a typhoid fever to treat. The peculiar typhoid facies was well marked. I put him on the treatment at my first visit and the result was very gratifying, his temperature reaching normal in eight days. It was some two weeks before he was able to work.

Miss F——, a school teacher. Her mother having told me how she complained of being so very tired and exhausted, I was not surprised when called to find nearly all the symptoms of typhoid present. I put her at once upon the treatment and after a few doses she vomited excessively. I then stopped the tablets and gave subnitrate of bismuth for a few hours, when, the stomach seeming quiet, the tablets were resumed, but again rejected. She was then put upon the sulpho-carbolate of zinc alternately with guaiacol carbonate, gr. iv., every four hours. Her bowels were kept open with calomel. She made a prompt recovery, temperature reaching normal in six days. She was out of school between two and three weeks.

I saw Miss G——, aged twelve, on Saturday with a temperature of 104° F., prescribed for the fever and gave a cathartic, supposing from the sudden invasion it would subside soon, and did not see her again. I was called the following Tuesday to find a temperature of 105.3° F., iliac gurgling, and splenic dulness as large as the back of the clenched fist and as distinct as over the liver. I put her at once upon the No. 1 tablet and followed the treatment faithfully. Thursday morning there had been six dejections and at 8:30 P.M. the temperature was 105.2° F. Friday morning there had been six more dejections and the temperature was 101° F. and next morning 98.5° F.; four days of treatment. The splenic dulness disappeared almost as rapidly as the high temperature and could not be detected on the second day of normal temperature. She made a steady but rather slow convalescence.

Mr. E——, a rather robust and corpulent travelling salesman, twenty-eight years of age, was attacked the day before I saw him with chilliness and severe pain in the head, back, and limbs, with muscular soreness. I found him October 5th with a temperature of 102.5° F., complaining very much of his pains. I gave a calomel purge and acetanilid in hot water for the pains, but next day found him with more fever in spite of the acetanilid. His temperature was 103.5° F. and he begged for something to relieve the pains in his head and back. There was no epistaxis and at this time no special tenderness in the right iliac region, but the expression of his face was that of a typhoid, and the severity of the pain and his peculiar complaint reminded me of the first case so much that I put him at once upon the tablet treatment and followed it faithfully, with the result that his temperature was normal in five days. I would say that after the first few days he developed considerable iliac tenderness and it was four weeks before he was able to resume his work. I believe this to have been a case of aborted typhoid fever, and that, too, in a man in whom everything favored the severest form had it taken its regular course.

I will present in this connection one case taken from the hospital records: W. J. T——, a young man, laborer. He consulted me at my office December 14th. Had some fever and general malaise. I did not feel positive as to the diagnosis.

December 15th I saw him at his boarding-house. I now found symptoms so suspicious that I put him upon the tablet treatment. Next day when I saw him the indications were still more marked and I sent him to the hospital. Here is the record made by the house officer: "He says ten days ago he had a chill; epis-

taxis twice last week, again this morning. Has had diarrhœa, body ached generally, tongue coated, abdomen slightly distended, rose spots, gurgling, and slight tenderness in iliac region of both sides, lips dry and cracked. Temperature, 102.6° F."

This reads like a typhoid record, more so than any of my private cases, and yet the result was the most satisfactory of all, the temperature reaching normal in three days. He was discharged well January 9th, having been in the hospital twenty-four days.

This comprises all the cases I have to present that I regard as aborted, and I am well aware that you can, and probably will, doubt the diagnosis. But I wish to ask one question. Are we justified at this early period of the disease in quietly folding our hands and allowing the bacilli to thrive and multiply in the alimentary canal until they have so affected the solitary and agminated glands that ulceration and sloughing become inevitable, not to mention the profound poisoning of the nervous system by the absorption of their ptomains? Shall we do this, I ask, merely to establish a diagnosis that cannot be doubted?

I firmly believe that the great majority of these bacilli—the intestines and stools always being found full of them—can be rendered inert and washed away at this early stage, and that by so doing the opportunity for making an accurate diagnosis may be forever lost. Dr. Woodbridge claims that under this treatment he has never failed to abort a case of typhoid fever seen before the eighth day. But the time of actual beginning must in many cases be involved in much uncertainty.

Osler, in speaking of the Brand treatment, says he gives the patients the benefit of the doubt and bathes them early, even before the diagnosis is established, though by so doing he has often bathed patients with other diseases than typhoid.

I can but think the principle involved is correct and should be applied with even greater freedom in this antiseptic and eliminating treatment of typhoid fever.

Mr. F—— had been sick in bed a week. On admission he had a hemorrhage, again on the fourth day, and two or three more succeeding it. Five days later he had a chill with temperature of 106° F., which was repeated next day. No complication being discoverable, he was put upon quinine and the chills or excessive temperature did not return. He had a severe run of the fever. There was a condition of paresis in one leg simulating phlebitis, but without swelling, though there was inability to move the limb. A little later there was retention of urine from paresis of the bladder and still later cystitis. He was ultimately discharged well.

Mrs. R—— had been sick eleven days on admission. To all appearances she was a very sick woman. Temperature, 104° F.; diarrhœa, five dejections the first day. Abdomen swollen and tympanitic. The house officer remarked it was a good case to test the treatment, upon which she was placed at once. The second day she had fifteen movements of the bowels and the temperature fell two degrees. While she was a very sick woman, her condition from that time was better. She had stomatitis, so we had to abandon the tablets, using the capsules and four grains of guaiacol carbonate every three hours alternately. We were not then so thoroughly imbued with the idea that the bowels should be kept open, and I think we erred in not using sufficient cathartics. She had a relapse and was put back upon the same treatment as at first, and made a good recovery.

Mr. D—— had been sick five weeks on admission, and from the history we were given to suppose he had malaria. We waited three days for the chill, and when it did not come and the temperature kept going higher we put him upon the treatment. He had a

slight recrudescence and a tedious convalescence, and also a rheumatic condition of one calf, which prevented his standing upon that leg for a week or more and when that was better the other was similarly affected. His recovery was ultimately good.

Mr. Sh—— had an ordinary attack, except as complicated with stomatitis and parotitis. He made a good recovery.

Mr. G—— had an attack of local peritonitis; other than that his case was uneventful.

The other charts simply showed the course the disease pursued in the sixteen uncomplicated cases and why we had the reputation of having mild typhoid. Among these would have been included the two following cases had not the charts been lost:

Carl —— admitted October 2d. The record says: "Temperature, 103.8° F.; numerous rose spots.

"October 9th.—Temperature dropped from 104.8° F. last night to 100.5° F. this morning.

"October 11th.—The morning temperature was 98° F. and the evening temperature was normal the 15th, i.e., in thirteen days."

Fitz —— was admitted October 12th with numerous rose spots. He had stomatitis from treatment, but nevertheless a normal temperature in nine days.

I am indebted to Dr. Greene for valuable charts from the hospital in this section, also to Dr. Farnham, too, for illustrating the effect of the treatment in children of five and nine years of age.

Before we leave the consideration of the charts I wish to call your attention to the fact that after the first few days of treatment in all the uncomplicated cases the temperature falls steadily and in some cases rapidly to normal in from eight to twenty days, the average being thirteen days. Also to the number of movements of the bowels and to what seems to be a fact that constipation ushers in relapses.

I wish also to call attention to the effect of the treatment upon the temperature. Observe how the temperature changed when the treatment was begun, becoming less vacillating, and how it resumed the same character when it was omitted. The same thing occurred in D——'s case when the treatment was commenced. Then observe how afterward throughout the whole course of the disease it did not vacillate like an ordinary typhoid temperature from morning to evening, the range being about one-half as great. In other words, the antiseptic and eliminative treatment removes much of the septic character of the disease, as shown in the daily range of temperature and its more or less rapid fall.

While I am a firm believer in hydrotherapy for the disease when indicated, I also believe that the necessity for its use is greatly diminished by steadily and persistently washing out the alimentary canal with antiseptics and cathartics, thus removing as far as possible the most fruitful source of the poisoning which is maintaining the high temperature that indicates the necessity for a further resort to hydrotherapy. Another thing that impressed me strongly while observing the cases under this treatment was the fact that in a short time after commencing it the dull apathetic look would give place to one of more intelligence and patients would seem to take more interest in what was transpiring about them. The tongue became moist early, as a rule, and seemed unusually clean throughout the course of the disease. We had none of the red, dry, and cracked tongues that we have been accustomed to see so frequently. Many seemed to have a desire for food, even with quite an elevation of temperature, and I have not hesitated to give stale bread, either toasted or with milk, and other things of similar character whenever they desired, if the tongue was tolerably clean and moist. Tender boiled chicken was usually allowed as soon as the temperature reached

normal. Tympanites has usually disappeared in a few days. This I suppose to be owing to the constant passage through the bowel of an antiseptic fluid which does not favor decomposition and the liberation of gases. Also to the fact that the bacilli in the canal are rendered inactive, washed away or destroyed, thus preventing the poisoning of the nerve centres by their toxins, which favors or even produces paralysis of the muscular coat of the bowel, thereby allowing distention.

Stomatitis occurred in quite a number of cases. When this was well marked the tablets were omitted and guaiacol carbonate in from three to five grain doses given alternately with the capsules. This removed all cathartics from the treatment, and we endeavored to compensate for it by the use of podophyllin, sulphate of magnesia, and the like.

I now think as I study the charts that in some of the cases we failed to keep the bowels sufficiently loose, and that probably the results might have been better if we had substituted in tablet No. 2 $\frac{1}{16}$ gr. of podophyllin for the calomel and podophyllin and used these in place of the guaiacol carbonate and various cathartics.

Dr. Shields says: "All cases of ptialism can be prevented by using a tooth powder of potassium chloride once daily." If this proves true, it is a matter of much value, as there is probably nothing so valuable as a cathartic in the disease as calomel if it can be used without producing stomatitis. It seems important to give the cathartic frequently in order to keep up a steady and constant action, thus changing in a measure the current of the fluids in the bowel from the mucous membrane to the lumen, thereby lessening the amount of septic absorption from the canal. One of Dr. Greene's patients had as many as twenty-two dejections in one day and twelve the next. Mrs. R— had fifteen, followed by a fall of two degrees in temperature, and one of my private patients had eleven. They certainly did not seem to be injured by them. Nausea was induced by the tablets in a few cases, but was soon overcome by a short suspension and giving bismuth for a few hours, when the treatment was usually well tolerated. Nothing was allowed to interfere with its continuance, not even hemorrhage, for we considered that a bowel emptied of its contents, both fluid and gaseous, would place the ruptured vessel in the most favorable condition for the hemorrhage to be arrested. A few cases, either from the irritation of the antiseptic or the frequency of the stools, developed a dysenteric condition, which was always relieved by a few injections of starch and laudanum without discontinuing the treatment. In none of my cases did hemorrhage commence later than the fourth day of treatment. To get the best results from the treatment the medicines must be given faithfully and persistently. Possibly this may explain why those who are enthusiastic in its praise get better results than those who are skeptical.

I do not wish any one to think that I consider this treatment perfect in its present form; on the contrary, I regard it as only in its infancy, and that as the mass of physicians shall give it a trial and learn what it can do in its present form, they will gradually have confidence and ability to make variations and observe results intelligently, until quite likely a more perfect method may be evolved. I would also enter a most respectful protest against experimenting before having tested it as it is, since thereby much harm may unintentionally be done by bringing discredit upon the method which it does not merit.

Now, gentlemen, in closing I wish to remind you that long before diseases were known to have germs it was thoroughly established that the stools of a typhoid patient contained a poison or ferment which, placed in

a privy vault, would infect the whole community. From this source, in a variety of ways, the germs are received into the alimentary canal and pass downward until they are below the inhibiting properties of the upper portion and arrive upon their native soil. Here in the contents of the lower portion of the ileum, always at a proper temperature for their rapid development, they multiply and grow in the greatest profusion. Their ptomains are absorbed, giving the malaise for the commencing fever and the fever itself as they become sufficiently abundant. The bacilli are taken up into the glands, both solitary and agminated of the mucous membrane, and there multiply and cause these parts to swell and ultimately to ulcerate and slough from the pressure. This does not occur until near the tenth day. Osler reports one case that had not ulcerated at ten days, and Phillips, two, one at fourteen and another at thirty-six days, yet autopsies were made and it was found that the patients died of typhoid fever, as shown by the swelling of the glands.

What killed them? Certainly not the extensive ulcerative destruction of the canal. Then it must have been the poisoning from the ptomains, and where were these developed? Undoubtedly some in the swollen glands of the mucous membrane, but chiefly in the contents of the canal itself, where everything in their history shows that they develop most rapidly and consequently produce the greatest amount of toxin. Now, if this is true of the germs of typhoid fever, its causes are always to a certain extent within our reach and under our control, and the reason why the treatment should be commenced early and continued faithfully throughout the disease must be apparent to every one.

Without detaining you longer I wish to call your attention to the frequency with which the bowels moved and to remind you that nevertheless the patients all recovered.

THE IMPORTANCE OF AN UNDERSTANDING OF MIDDLE-EAR DISEASE BY ALL PRACTITIONERS, WITH A REPORT OF SOME CASES IN WHICH INEXCUSABLE ERRORS HAVE BEEN MADE.¹

By RICHARD FROTHINGHAM, M.D.,

AURAL SURGEON, METROPOLITAN THROAT HOSPITAL, AND A SENIOR ASSISTANT SURGEON, THROAT DEPARTMENT, VANDERBILT CLINIC, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

ON account of the anatomical relations of the middle ear and the gravity of some of the results of middle-ear disease, as regards not only permanent loss of hearing but also danger to life, no part of the body is of more importance to all practitioners; and still there is no branch of medicine about which the majority of physicians know so little.

Besides destroying the organ of hearing and causing death, ear disease may result in permanent paralysis, disturbances of co-ordination, or it may affect the organs of sight, taste, and smell.

In most medical schools very little attention is paid to the teaching of diseases of the ear, and students, as a rule, have very limited clinical opportunities. Although grave and fatal cases are sure to come into the hands of all practitioners, there is no examination in this branch of surgery in most medical schools. Consequently, the average student pays little or no attention to diseases of the ear. Now that a four years' course has gone into effect in so many medical schools in this country, all things point to more thorough teaching and better clinical advantages in all special departments; and it is to be hoped that the ear will no longer be so slighted.

¹ Read before the Harvard Medical Society of New York, May 25, 1895.

Most medical men have a better idea of all other special branches, even including diseases of the eye; but if one of their patients has eye trouble, he is much less apt to tamper with it than with the middle ear. With the best intentions, the average physician assumes the responsibility of treating all acute and suppurative diseases of the ear, believing himself fully competent to handle such skilfully.

From childhood he has been taught to consider ear-ache and running ears as naturally of frequent occurrence but of minor importance, and commences his medical education with but little respect for the diseases of the ear. An examination on this subject not being compulsory, he oftentimes neglects the lectures and ignores this important branch of his profession, not even acquiring sufficient knowledge to appreciate their possible danger.

The correction of this grave evil lies in the hands of the faculties of the medical schools, who, by requiring all students to pass a rigid examination in aural diseases, would do much to benefit a long-suffering public.

The eye being on the surface, patients can see acute trouble; or, if there is a disturbance of vision, they realize the gravity of the case and are very apt to seek the advice of a specialist even without consulting their family physician. On the other hand, the tympanic cavity is situated so deep in the skull that the patients cannot see for themselves, and do not appreciate the gravity of their case; and if they have an acute or suppurative ear disease are well satisfied to place themselves in the hands of their family medical adviser. Comparatively few cases of acute or suppurative ear disease come into the hands of a specialist until either the patient's condition has become so serious that they insist on other advice, or the family physician, having exhausted his remedies, gives the thing up as a bad job—which, by the way, he is very loth to do. Patients dread becoming blind, but patients with ear trouble do not realize their danger. In eye disease there is little or no danger to life; but, in neglecting proper aural treatment, a patient runs the risk of death or permanent injury to the organ of hearing.

Children especially are neglected. Their little ears may ache ever so hard, but so long as the general practitioner assures the family that "pain will pass away or the ear discharge, and in children discharge from the ear is harmless and usually takes care of itself," the parents are satisfied. Adults stand a certain amount of pain; then, their patience becoming exhausted, and having obtained no relief, they seek other advice. Ear disease in infants is often overlooked.

Anatomy.—To emphasize the importance of disease of the middle ear, let us briefly consider some of the anatomical relations of its parts as given by different authorities.

So intimately are the middle ear and external auditory meatus associated in their diseases, and as in all middle-ear disease the condition of the canal must be considered, I also give its anatomical relations.

The External Auditory Canal.—The external auditory canal is in relation anteriorly and inferiorly with the parotid gland, suppuration of which may discharge through the meatus. Anteriorly it is also in relation with the posterior wall of the articular fossa of the inferior maxillary bone.

The posterior wall is made up by the mastoid process; and pus from the mastoid may come through this wall.

Its superior wall forms a portion of the middle cranial fossa and is covered by the dura mater. This wall may be very thin, and otitis externa may produce disease of the brain.

The Middle Ear.—The middle ear consists of the tympanic cavity, membrana tympani, the ossicles, Eustachian tube, and mastoid process. The mucous membrane lining these parts is continuous with that of the pharynx, and acts as periosteum. This explains how easily ulceration of the mucous membrane will cause caries; and a spot of caries the size of a pin's head will permit of extension to the cranial cavity and fatal consequences.

It is especially the tympanic cavity that concerns all practitioners.

The Tympanic Cavity.—The tympanum is an irregular prismatic cavity, enclosing the auditory ossicles, and measuring about half an inch from above downward and from before backward, and from one-twelfth to three-sixteenths of an inch from without inward. It is situated within the petrous portion of the temporal bone, immediately above the jugular fossa and below the cerebral membranes, the carotid canal lying in front, mastoid cells behind, external meatus externally, and the labyrinth internally. It is in relation with more structures of importance than any cavity of equal size in the body.

The fact that there are some twenty communications with the tympanic cavity readily explains the numerous channels for invasion of middle-ear disease to deeply seated and important parts.

The relations and conditions of the different walls of the tympanic cavity are of sufficient importance to be considered separately.

The superior wall forms the roof of the mastoid and Eustachian tube, and is the partition between the cranial and tympanic cavities. Its thickness varies, sometimes being very thin or entirely wanting, the mucous membrane of the tympanum being in contact with the cerebral membranes and forming part of the cranial cavity. In infants the suture petro-squamosa is open, but in adults this is usually closed.

The inferior wall separates the tympanum from the jugular vein. This wall also varies in thickness, sometimes being membranous.

The anterior wall lies close to the carotid canal. At its upper part the Eustachian tube opens into the tympanic cavity.

The posterior wall has important relations to the facial nerve, as the eminentia pyramidalis containing the stapedius muscle is connected with the Fallopiian canal by fissures. Therefore, in caries of this wall, the facial nerve is exposed to danger. In the upper part of this wall is the opening between the mastoid and tympanum.

The membrana tympani is the dividing line between the middle and external ear. Its function as a protective to the delicate structures of the middle and internal ear is not of secondary importance to whatever part it takes in the transmission of sound.

The inner wall of the tympanic cavity forms the dividing line between the tympanum and labyrinth.

Its relations and landmarks are the fenestra ovalis in the upper posterior part, below and posteriorly the fenestra rotunda. Between and in front of the two fenestræ is the promontory. Vertically above the promontory is Jacobson's nerve, and above and behind the fenestra ovalis is a portion of the Fallopiian canal containing the facial nerve.

Caries of the inner wall may cause suppuration in the labyrinth and extension into the cavity of the skull.

The facial nerve, being separated by a thin plate of bone which may be deficient in places, is easily inflamed or destroyed.

The Mastoid.—The relations of the mastoid process to the lateral sinus and cranial cavity should be remembered by all. Sometimes the petroso-mastoid suture is not obliterated, and pus may make its way through it to the cranial cavity.

The lateral fossa or sulcus forms the inner and posterior wall of the greater part of the mastoid cells. Usually this wall is strong, but it may be very thin or perforated.

Vessels and Nerves of the Middle Ear.—Owing to the free anastomosis between the fibres of the sympathetic, trifacial, pneumogastric, and glosso-pharyngeal, and the nerves of the middle ear, either reflex aural symptoms may arise from disease in other parts of the body or reflex symptoms of other organs may be due to disease of the ear.

The arteries of the tympanic cavity are derived from the external and internal carotid, middle meningeal, and stylo-mastoid. Of the blood supply little need be said, except to remind you of the free anastomosis between the vessels of the tympanum with those of the labyrinth and brain. This is often the channel for a purulent inflammation.

Many general practitioners are, and all should be, perfectly familiar with the normal landmarks and methods of examining the middle ear, and perfectly able to recognize and treat all cases of acute or suppurative disease with credit to themselves and full justice to their patients. They can do a paracentesis or mastoid operation if necessary, and know full well when the case demands such surgical interference. It does not require any great amount of training or special skill for any man to acquire sufficient knowledge to become familiar enough with the ear to be able to examine a case and recognize the normal landmarks of the drum membrane. This is more than half the battle. Very soon he would notice any deviations from the normal picture in the field, such as foreign bodies or cerumen in the canal, polypi, granulations, perforations, congestions, bulging, or retraction of the drum membrane. When it comes to recognizing the finer changes within the tympanic cavity, the result of suppuration or adhesions; changes in the ossicles, the result of misplacement or caries; and the finer diagnostic points between obscure diseases, special skill and long experience are requisite, and this is not within the scope of the busy general practitioner.

My experience leads me to believe that most men, in examining the ear, hold their speculum at the wrong angle; and so, instead of seeing the drum membrane, obtain a beautiful view of the posterior wall of the meatus.

The cases I report will well illustrate some inexcusable mistakes made by general practitioners, many of them excellent men and graduates of our best schools.

In the treatment of disease of the ear, treatment of the nose and throat should go hand in hand, and together they should be treated as one organ. The aurist who is not a thorough throat man can obtain but poor results.

Prognosis of Middle-Ear Diseases.—While speaking of the necessity of a more thorough understanding of middle-ear disease by the average man, a few words on the prognosis and result of treatment may not be amiss.

Excluding chronic middle-ear catarrh, the results from treatment in middle-ear disease are most satisfactory, nay, even brilliant. In no branch of medicine or surgery are they better.

Chronic middle-ear catarrh usually comes on so slowly, and the loss of hearing is so gradual, that it is quite imperceptible to the patient. He becomes quite deaf before he realizes that the hearing is affected. In the mean time the disease has been running on from two to ten or more years before the patient seeks treatment. The patient is told by his family and friends that he is getting deaf, but does not believe it and replies that "people mumble and do not articulate distinctly." On finally awaking to the fact that

he is deaf, it is too late to accomplish much by treatment. Usually all that can be done is to get back what hearing has recently been lost, and to help the patient keep what hearing still remains. The more acute the chronic middle-ear catarrh in its onset, the better the prognosis in individuals previously healthy.

When chronic middle-ear catarrh is due to disease of nose or throat and is seen early, we can stop the disease and restore in large measure what hearing has already been lost. When acute middle-ear catarrh is properly treated, we can restore the hearing. It is in the treatment of acute and chronic middle-ear suppuration with or without granulations, polypi, and other complications, that we can expect and do get brilliant results.

Statistics show that about two-thirds of all ear diseases are of the middle ear, and that about thirty per cent. of all ear diseases are suppurative; also that an average of about seven-tenths of one per cent. of all ear cases treated in ear hospitals are affections of the mastoid.

According to Field, between one and two per cent. of all cases of aural suppuration are supposed to result fatally from intracranial complications.

Barker records that out of eight thousand and twenty-eight deaths from all causes in three large London hospitals during twelve years, forty-five cases were due to disease of the temporal bone.

Four factors are to be taken into consideration in the prognosis of suppurative middle-ear disease: Prognosis as to life, stopping discharge, closing of perforation, restoration of hearing.

Acute middle-ear suppuration, properly handled, rarely causes intracranial complications or results in death. The danger of septicæmia is slight. Under proper treatment the discharge stops, perforation closes, and the hearing usually becomes normal.

In scarlet fever and diphtheria prognosis is more doubtful. In these cases the amount of destruction decides the result. Ulceration may be rapid and destroy all of the drum membrane, and extend to the ossicles, and they may be thrown out with the discharge.

Prognosis in acute mastoid disease, except in specific and tuberculous individuals, is good.

In healthy individuals with chronic suppuration, we can stop the discharge. The closing of the perforation depends on the amount of destruction of the drum membrane and the condition of the edges of the perforation. If the perforation remains open there is always danger of a recurrent attack. The amount of hearing remaining depends on the condition of the drum membrane and ossicles.

Death, as a result of a neglected chronic otorrhœa, is by no means uncommon. It seems to be pretty generally agreed to by all aurists that as long as a discharge from the ear exists there is danger to life.

C. H. Burnett says that "so long as a chronic purulent discharge comes from an ear, the patient's life and hearing are in danger, and unless the otorrhœa is cured the disease surely tends to extend to the brain."

Schwartz says: "As long as purulency exists, even though it be so slight that no discharge from the canal is seen, there is danger to life. The symptoms of fatal disease may appear with unexpected suddenness when the otorrhœa has, perhaps, existed for many years, with no perceptible detriment to the general health, and in cases also in which no caries exists."

Urbantschitsch states that "practical experience teaches that individuals with chronic otorrhœa do not, as a rule, reach advanced age."

Death may result from meningitis, cerebral abscess, septicæmia, general pyæmia, septic thrombo-phlebitis, hemorrhage.

Thrombosis and phlebitis are most common in the lateral sinus, but may occur in the superior or inferior petrosal sinus.

Ulceration through the anterior wall of the tympanic cavity may cause erosion of the internal carotid artery. Fortunately this is rare, about twenty cases having been reported.

Ulceration through the inferior wall of the tympanic cavity may cause fatal hemorrhage from the internal jugular vein. Also there may be hemorrhage from the middle meningeal artery, and lateral and petrosal sinuses.

The stand taken by most life-insurance companies shows the respect with which they regard otorrhœa as a factor in causing death. By the best of them it is agreed that all persons with chronic middle-ear suppuration should be rejected. Some companies believe in assuming the risk at an advanced premium. Some companies reject individuals in whom there is a permanent dry perforation of the drum membrane, and other companies accept such a person if there has been no discharge from the ear for a certain number of years. Of course, during an acute suppuration, no person is accepted; and some companies refuse to assume the risk if there is a history of recurrent attacks of acute suppuration, even though the drum membrane is intact and other conditions are apparently normal.

Unrecognized Acute Middle-Ear Suppuration Followed by Meningitis.—In August, 1894, a house officer in one of our best New York hospitals requested me to examine this case: A woman, aged thirty, poorly developed and nourished. Her right ear had been useless since childhood, the result of suppuration, but had not discharged since that time, and was found to be perfectly dry. The left ear had never troubled her until the present attack. Some ten days before I first saw her she had pain in the left ear; since which time the pain had been steadily on the increase, and for the last few days she had been unable to sleep, temperature running from 101° to 103° F. for several days. Physical examination negative. On examining the left ear, the meatus was found very much congested and swollen in its upper posterior portions; the drum membrane only so around the extreme periphery. The rest of the drum membrane was pale yellowish, with great bulging, and pus was seen through it in the tympanic cavity. So great was the pressure of this pus that all blood was apparently squeezed out of the vessels of the drum membrane. Immediate paracentesis was advised. The house officer did not have the authority to give me permission to do even so slight an operation without first consulting his "visiting," a fine and very busy practitioner. That afternoon the "visiting" examined the case; and he, seeing no great inflammation or cause for operation, decided to await further developments. Three days later he decided to have the ear lanced, and called in the visiting surgeon to operate. The surgeon punctured the ear in two or three places, but got nothing but blood. Probably forgetting the direction of the meatus, he neglected to lift the auricle upward and backward, and, his speculum being at a wrong angle, his knife went into the posterior wall of the meatus. This gave the patient no relief. She developed meningitis and died.

Acute Mastoid Disease, Diagnosed as "Cellulitis."—Mary —, aged twenty-five, a strong and healthy woman. Last July, while at a summer resort on Long Island, she had an attack of erysipelas and developed an acute ear trouble. The disease extended into the mastoid, and her sufferings for the four weeks before I saw her were very great. Her physician, a New York man, having a summer practice at one of the fashionable resorts, attributed the great pain, extending all over the side of the head, the extensive

mastoid œdema, and sensitiveness on pressure, to a cellulitis resulting from the erysipelas. He allowed this condition to go on for some four weeks, all the time the swelling and her sufferings being on the increase. Then he finally suggested a change of air. She came to New York and consulted another man, who viewed the case in much the same light as his predecessor. One week later she fell into my hands. I found the walls of the left meatus nearly in contact, from great œdema of the upper posterior wall of the meatus, and œdema and apparent fluctuation over the mastoid, the auricle standing out prominently. Under ether I did a paracentesis and mastoid operation. Some two ounces of pus were found in the tissues over the mastoid. The external cortex of the mastoid was solid and no sinus was present, but a spot of inflamed, discolored bone was seen. This spot was very soft, and a drill easily penetrated it. On going in some one-fourth of an inch, pus welled out of the bone under great pressure. The opening was enlarged and a large drainage tube inserted. There was no pain after operation, and the patient made an unusually rapid recovery.

Furuncle of Canal, Diagnosed as "Mastoid Disease."—CASE I.—Last May I was called upon to do a mastoid operation in this case: A woman, aged twenty, had severe pain in and around the ear for three days. On examination I found the auricle congested and sensitive to the merest touch. The movements of the jaw in mastication caused excruciating pain, as did also all movements of the auricle. There was no tenderness over the mastoid except when the auricle was touched. A large furuncle of the posterior wall of meatus was found. This was incised, with evacuation of its contents. Relief was immediate, and in three days the patient was entirely well.

CASE II.—A male, aged thirty-five. History and condition of ear the same as in above case. Patient had been to the hospital and was told that he would have to be admitted, an operation performed, and it would be two weeks before he could leave the hospital, as the ear would have to be opened from behind. Incision gave the same relief and result as above.

Acute Middle-Ear Suppuration Diagnosed and Treated as "Neuralgia."—CASE I.—Miss C—, aged twenty-six. Never had ear trouble before. In May, 1893, during an attack of acute coryza she first had pain in right ear four days previous to my first visit. Pain in the ear steadily increased and extended into the mastoid and all over the side of the head. For two nights she had been unable to sleep. When her sister came for me, she reported that the patient had been delirious all night. Her physician had several times examined the ear, and pronounced it "neuralgia," as the drum membrane was perfectly normal. On my arrival I found her condition quite serious. Pulse, 160; temperature, 103.4° F.; and she was excited and feeble. Great mastoid tenderness, and the chances were that the case would require a mastoid operation. Examination showed the deeper part of the meatus filled with cerumen, no portion of the drum membrane being visible. On removing the cerumen the drum membrane was found swollen, congested, and bulging, with two small bullæ on it. These were incised and a free paracentesis made, after which there was abundant serous discharge. One hour later temperature was 100° F. Patient went to sleep soon after the operation. Her ear trouble yielded nicely to treatment (leeches, ice, and douching), and in one week's time the ear was entirely well.

CASE II.—Miss McG—, aged twenty-two. History and condition about the same as in the last case, except that there was no cerumen and that her trouble had been running on some four weeks. She had been in the hands of two men, both of whom assured her

that "the ear had not gathered and would not gather." After a paracentesis this case for a week yielded nicely to treatment, but mastoid inflammation developed and operative interference became necessary and was advised. The family would not consent to a mastoid operation, and the last I heard of the case she was trying the "faith cure."

Otalgia Dentalis Diagnosed as "a Gathering in Ear."—CASE I.—Girl, aged twelve. Bad pains in the left ear for three weeks. The ear had been syringed and poulticed for over two weeks. The child was examined by her medical adviser half an hour before I first saw her, his verdict being that the "ear is nearly ripe; go on in the same way and the ear will soon break." My examination revealed a normal drum membrane. I discovered a very bad tooth. I advised its removal and promised relief. The tooth was extracted and her sufferings ended.

CASE II.—Mrs. A—, aged forty, had pain in her ear for some weeks. She was examined by a good general practitioner and her trouble was pronounced by him "a gathering in the ear," and he insisted on immediately lancing it. The patient did not like the idea, and, as I had treated one of her children for ear trouble, she came directly from him to my office. I again found a normal drum membrane and a bad tooth, after the removal of which the same result followed as above.

Acute Middle-Ear Suppuration Right, but Same Disease on Left Overlooked.—Willie L—, four months old, a very badly nourished and weak child, was first seen by me in July, 1894. History: The child did very well until he was about four weeks old, except that he had "snuffles." Then the child commenced to be very fretful and restless, cried a great deal, and never slept soundly. The child became very much emaciated. Three weeks before I first saw the child his right ear commenced to discharge, but there was no improvement in his general condition. All this time the family physician was in constant attendance. At the appearance of discharge from the ear he said: "Let the ear alone and the child will soon be well now." For all this the child was steadily going down hill. Two weeks later a throat man who does considerable ear work was consulted. At this time there was a profuse muco-purulent discharge from the right ear. As after his having treated the child for a few days there was no improvement in the child's restlessness or general condition, he referred the case to me for an opinion as to the cause of the baby's apparently continued pain. On examining the right ear I found a large perforation of the drum membrane, with free discharge and no bulging. The left drum membrane was very much bulged and pus could be seen through it in the tympanic cavity. I wrote to my friend and advised an immediate paracentesis of the left drum membrane. Three days later the child was again sent to my office; the doctor, seeing no indications for paracentesis, did not operate. The child's general condition was much worse, but the condition of his ears remained unchanged. I emphasized my former advice. Next day I was requested by the doctor to take charge of the case. I made a curved incision of the drum membrane, upon which there was free escape of muco-pus. The child quickly became quiet and went to sleep before the nurse left my office. The child rapidly gained his strength. Later I performed an adenoid operation, and to-day the baby is as healthy a specimen as one would wish to see.

Polypus from Shrapnell's Membrane the Unrecognized Cause of Head Symptoms.—Woman, aged fifty, suffered from vertigo and dull pain with fulness all over the left side of head for some two years. Treated by family physician for head trouble and change of life. She was assured that she had no ear

trouble, although every few days she noticed a stain on the towel after cleaning the ear. This was "softened wax," the doctor reported. On examining the ear a polypus the size of an ordinary pea was seen hanging down from Shrapnell's membrane. This was removed, and through the perforation of Shrapnell's membrane the attic was seen to be filled with pus and desquamated epithelium. The attic was thoroughly cleansed with a middle-ear syringe, introduced through the perforation. The woman's vertigo and head symptoms were relieved.

Polypus of Ear, Diagnosed as "Chronic Catarrhal Disease."—Mrs. M—, aged sixty, suffered from tinnitus, fulness, and pain all over the left side of head some five years, and felt sure that she was going insane. She had been treated off and on for chronic catarrhal deafness for several years by one of the best doctors in a favorite watering-place. He last treated her by catheterization for her "retracted drum membrane" two days before I first saw her. On examination I found a very large glistening polypus entirely filling the inner half of the external meatus. This was removed and the drum membrane found to be almost entirely destroyed. The symptoms were relieved, and the patient now feels that her head and brain are as good as any one's.

Acute Middle-Ear Disease with a Bulla of Drum Membrane Diagnosed as "a Malignant Growth."—A woman, aged thirty-six. History of earache for three weeks without treatment. Referred to me by a physician who had made a diagnosis of sarcoma from the great pain and its very rapid growth. On examination I found the right meatus almost filled by a large bulla. This was incised and large clots were removed, after which, as there was some bulging of membrana tympani, a paracentesis was done. Serous discharge. Relief of pain. Convalescence rapid and uneventful.

Dried White Desquamated Epithelium in Canal. Diagnosis Made that "Ossicles were Coming Out."—A nervous woman, aged twenty-five, with a history of deafness with pain in right ear for several months. She was examined by her physician, and he sent for me in a great state of excitement, as he found that the ossicles of the ear were surely coming out. He had probed them, and was positive that they were bones of the ear. On examination I found the inner third of the meatus filled with a whitish, irregular mass of hard, dry, desquamated epithelium. This was removed and the ossicles were seen intact. Patient had a small, dry perforation of Shrapnell's membrane, from which no pus escaped. Pain and deafness were relieved.

Were I to enumerate the number of patients I have seen with perfectly intact drum membranes, who had been told by physicians that the ear drums were entirely gone, I would more than try the patience of this society. Some of the drum membranes were perfectly normal, others in various stages of thickening, retraction, cicatrization, or calcification.

On the other hand, patients without a vestige of drum membrane or a sign of an ossicle, in whom on examination the entire inner wall of tympanic cavity could be seen, have been assured that their drum membranes were perfectly normal.

12 EAST THIRTY-EIGHTH STREET, NEW YORK.

Inoculation against Rabies in Vienna.—During the years 1894-95 the number of patients who underwent a course of preventive treatment of rabies at the Rudolf-Stiftung in Vienna was one hundred and twenty. The anti-rabic department, where the treatment is the same as that employed at the Pasteur Institute in Paris, is under the care of Professor Paltauf. There were no deaths among those treated by inoculation.

FORMALIN AS A PRESERVATIVE.¹

By H. A. L. RYFKOGEL, M.D.,

SAN FRANCISCO, CALIF.

CURATOR OF THE MUSEUM, MEDICAL DEPARTMENT, UNIVERSITY OF CALIFORNIA, AND ASSISTANT DEMONSTRATOR OF ANATOMY, MEDICAL DEPARTMENT, UNIVERSITY OF CALIFORNIA.

To find an ideal preserving fluid has long been the aim of those taking an interest in the care of specimens of organic life.

Such a preservative must not alter the preparation in any way, it should cause no shrinkage nor hardening, the color of the object ought not to change, the microscopic as well as the macroscopic appearance must be preserved, the fluid should be non-inflammable and obtainable at but little cost. As yet no combination has fulfilled all these indications, nor is it likely that any ever will; for preserving fluids are usually such by virtue of one of these very objections, if such it really be, namely the hardening of albuminous material.

Of necessity all preserving fluids must have antiseptic qualities and many such, as alcohol and glycerin, are hygroscopic as well. This last quality is of course not an advantage, owing to the great shrinkage that occurs on the withdrawal of any water from animal tissues.

It is by the presence of these qualities that we must judge the value of the different media in use. Thus, solutions of boric acid, four per cent., or carbolic acid, one to two per cent., are simply antiseptic. Any object placed in these will indeed not suffer putrefactive changes, but after a time will become macerated and practically worthless. Glycerin is hygroscopic and slightly antiseptic. It alters by shrinkage and is too costly for ordinary use. Alcohol is hygroscopic, antiseptic, and coagulates albumin. It therefore both hardens and shrinks the specimens. It also alters by dissolving out many of the organic pigments. Finally, solutions of formic aldehyde are antiseptic. They harden albumin, but cause no shrinkage, and effect animal pigment but slightly.

Of course all fluid preservatives alter the appearance of tissues to a certain degree by the withdrawal of blood.

The specimens we show you have been kept in formic-aldehyde solution or formalin, which appears to overcome many of the objections mentioned above.

Formic aldehyde, a gaseous body discovered in 1863 by Hoffmann, while passing methyl alcohol and air over hot platinum, is one of a peculiar series of chemical compounds which differ only in the amount of oxygen they contain. The first of these is methane, or marsh gas, of which the chemical formula is CH_4 . The second is methyl alcohol with a formula of CH_3O , and the third, methylenglycol, is represented by the formula CH_2O . If we now extract from this last one molecule of water, we have the formula of formic aldehyde, CH_2O .

Formic aldehyde is a gas, colorless and possessing a very pungent odor. When inhaled it is very irritating, quickly setting up a coryza or bronchitis. Its point of saturation in water is forty per cent., and it is this saturated solution that is sold under the name of formalin by Schering. We probably have here a solution of methylenglycol, for, as shown above, formic aldehyde plus one molecule of water gives us methylenglycol, thus: $\text{CH}_2\text{O} + \text{H}_2\text{O} = \text{CH}_2\text{O}_2$.

On account of its antiseptic properties, discovered by Blum, it has been used in many diseased conditions dependent on pathogenic germs, but it is of its uses as a preservative and fixing agent that we now

wish to speak. These, as mentioned above, depend on its antiseptic powers and ability to harden protoplasm.

Solutions of one-per-cent. strength, *i.e.*, one volume of formalin to forty of water, preserve gross specimens of tissue indefinitely and so thoroughly that microscopic sections may be prepared therefrom at any time. Solutions of this strength will not, however, fix the cells so as to show fine intracellular structure. Still it is the architecture of the tissue, as it were, that most interests the pathologist, and this will be perfectly shown.

Solutions of even less strength may be used, but with less satisfactory results as regards preservation of color and minute detail. When the object to be preserved has many delicate colors that must be shown, a stronger solution, *e.g.*, four per cent. to eight per cent., had better be employed. Bodies of insects and reptiles, fruit and flowers should thus be preserved.

You have all noticed that the slime or mucus that covers the bodies of certain fishes, reptiles, etc., and some pathologic specimens becomes converted into white stringy masses when the animal or tissue is placed in alcohol. This does not occur with formalin in solutions stronger than one in forty (one per cent.); so that any slime or mucus that covers specimens placed therein remains transparent.

Formalin gives beautiful results in the preservation of the central nervous system, showing very distinctly the white and gray matter. For this purpose, however, it has two objections. First, it causes a certain amount of swelling; second, the gray matter becomes very brittle, so that small pieces are broken off in handling. These may both be remedied by making up the one per cent. solution of formalin in fifty per cent. alcohol, thus:

R Formalin		1 part.
Alcohol,		
Water		50 parts.

This at first glance may appear expensive, but it is not so, for a single immersion will suffice, owing to the great rapidity of penetration of the formalin. Of course if alcohol alone were used it would have to be changed one or more times to obtain a good result.

If a strong solution of formalin be injected into the digestive tube and carotid artery of a small animal, The specimen may be left hanging in the open air for many months without undergoing change.

Blanchard has preserved leeches in the fluid and found no alteration in the delicate coloration of the animals after a year.

Egg albumen placed in formalin, four per cent., solidifies and becomes slightly opalescent. If it is now boiled it will not change in appearance.

Formalin has also been of great use to teachers of bacteriology demonstrating cultures in gelatin. For, if the vapor of formalin be introduced into a test tube in which a culture is growing, it immediately arrests the growth of bacteria. Moreover, the gelatin which has been liquefied by the bacteria is again solidified without alteration of appearance. Thus a culture may be kept in any stage of growth desired.

As a fixing agent in solutions of two per cent. to five per cent. it far surpasses alcohol and almost equals the more costly fixing agents, such as osmic acid, etc., killing as it does the cells before any change can take place in the finest intracellular structure. For example, it has been used instead of osmic acid in Ramon y Cajal's method for nervous tissues with better results.

Durig has used four-per-cent. formalin as a mordant instead of aniline-oil water.

Cullen, of Johns Hopkins, has devised a method for making frozen sections permanent by means of formalin. He places the section in formalin, four per cent.,

¹ Read before the Alumni Association of the Medical Department of the University of California, April, 1896.

three to five minutes; alcohol, fifty per cent., three minutes; alcohol absolute, five minutes. Cullen finds sections prepared in this manner in twenty minutes after an operation as definite for diagnostic purposes as those prepared by the ordinary methods which take several days.

To recapitulate, the advantages of formalin over alcohol are as follows:

1. Alcohol by withdrawing the water from a specimen causes great shrinkage. Formalin, acting only by changing the protoplasm, causes very little shrinkage.

2. Alcohol dissolves out most organic pigments and so greatly alters the appearance of objects. Formalin does not do this to any extent.

3. The price of alcohol is nearly \$3 a gallon; that of one-per-cent. formalin solution about 30 cents.

4. Alcohol is very inflammable. Formalin, being a watery solution of a gas, is not so.

5. Alcohol by changing mucus or slime to white strings spoils the appearance of objects covered by this material. Formalin by leaving mucus and slime transparent is free from this objection.

The objection to formalin is the irritating quality of its vapor when inhaled. This is, however, not troublesome in the solutions ordinarily employed.

The specimens shown well illustrated the advantages of formalin. Two were specimens of a pneumonic lung, one in alcohol, the other in formalin. From the external surface of the one in alcohol the delicate mottling and striping had almost vanished. On the contrary the specimen in formalin—in this case one per cent.—was almost unaltered.

In another jar was a uterus from a case dead of purpura hemorrhagica. This was placed in a four-per-cent. formalin solution in order thoroughly to harden the blood clot in the interior of the uterus. After four weeks the uterus was carefully cut across and the specimen was ready. Upon examination it was seen that the blood clot formed a perfect cast of the cavity. Neither the uterus nor the clot had shrunk to any appreciable degree.

Colloid material in the Graafian follicles remains clear and has not decreased in volume; one of them is filled with a clot which, like that in the uterus, completely fills the cavity.

Had this specimen been prepared in alcohol every thing would have been shrunk and distorted. The clot would not have formed such a perfect cast of the uterine canal and the contents of the Graafian follicles would have appeared as opaque balls or strings filling a small part of their interior.

1546 HOWARD STREET.

Physicians Should Work Less.—Dr. Kortright, in the *Brooklyn Medical Journal*, says that arterial sclerosis is a common cause of death in physicians. The lesson that we should learn from our deceased colleagues, he states, is not to work too long. When you find your arterial tension increasing, your temporal artery becoming tortuous, your radial growing hard, especially if you have a little palpitation and pass an increased amount of limpid urine, whatever your years, know that old age is upon you. Henceforth shape your life like one that is old. Curb your ambition. Be content with a small practice. Reduce your expenses. Give up your night work. Decline confinements. Take a long vacation in summer. Retire early. Eat abstemiously. Drink not at all. Sell your horse. Take a great deal of moderate exercise in the open air. Watch the functions of the skin. Guard against a chill. Cultivate an even disposition. Study to be quiet.

A DANGER IN FILTERING URINE WITH TALC.

By BRANDRETH SYMONDS, A.M., M.D.,

MEDICAL EXAMINER FOR THE MUTUAL LIFE INSURANCE COMPANY OF NEW YORK.

THE difficulties in testing for albumin in the urine are too well known to be enumerated here. The fallacies to which our tests are liable and the means of avoiding and overcoming these are generally well understood. If the albumin is abundant there is no liability of error. When urine shows a distinct white cloud on boiling which is not dispelled by the addition of nitric acid, and when also a distinct white ring is instantaneously formed at the junction of the same urine and cold nitric acid—the so-called Heller's test—it is not necessary for us to examine further in order to predicate the presence of albumin in that specimen of urine, or to seek more delicate tests for this particular case. The accuracy of combined positive results with these two tests cannot be questioned. When, however, the amount of albumin is less, so small that the cloud on boiling is a faint one and needs good light and a dark background in order to discern it, and the contact test with nitric acid shows negative results even after standing for half an hour, then our tests may give certain fallacious reactions against which it is necessary to be on our guard. The substance which it is most difficult to exclude under these circumstances is mucin. This is present in nearly all urines, even of men who are apparently healthy. The test for it is very simple and delicate. If mucinous urine is allowed to overlie acetic acid, a diffused white ring is quickly formed at or just above the junction of the two fluids. This reaction is also produced by means of citric,¹ picric,² tartaric,³ and dilute mineral acids. The latter in the slightest excess are said to dissolve the precipitate. The delicacy of these reactions with mucin causes Oliver to say: "All acid reagents employed for the detection of albumin in small quantities by the contact method are open to the fallacy of the mucin reaction."

Each writer agrees with all the others in recognizing this difficulty in testing for albumin with all tests but his own. As regards his own test, either it does not react with mucin or there are certain easy modifications by which this difficulty can be absolutely avoided, but no other test besides his is to be countenanced, as all the others are inaccurate or not delicate. This is the story that is told by a dozen writers on this subject, affording thereby much amusement to that unbiassed physician who reads them all. I have tried nearly all these contact tests, and must agree with the majority as regards the accuracy of each test. I consider each of them liable to give a reaction with mucin which cannot be distinguished from that with albumin.

About two years ago a method for avoiding these reactions with mucin was introduced to the profession by a well-known firm of apothecaries, who also made a specialty of urinalysis. This method, which received the endorsement of Grey,⁴ was as follows: "Clarify the urine by adding about sixty grains of powdered French chalk, purified for this purpose, to an ounce of a mixture of two parts of urine and one of distilled water; shake all thoroughly together and pour upon a small four-ply filter, which has been previously wetted with distilled water, throwing away the first portion of about one drachm, and returning remaining

portions to the filter, until the filtrate is perfectly clear. This separates the bacteria and the suspended mucin from the mucus of the mucous membrane."

I used this method for some time for clarifying urine which was partly decomposed, before my attention was drawn to its faculty of separating out also mucin. This seemed very reasonable, as I had previously noticed its ability to remove a large part of the urinary coloring-matter, which is more soluble than mucin. For a short time this method gave great satisfaction. Then the unpleasant thought arose that if talc possessed the power of removing mucin and urinary coloring-matter, why does it not also remove albumin? I submit herewith the experiments which were undertaken to determine this. Esbach's albuminometer was used for the quantitative investigations in all cases. Even if this is only approximately accurate, it is reliable enough for purposes of comparison. All the tests in each experiment were made on the same evening and the results were carefully checked the next evening, thus insuring accuracy for purposes of comparison. The urine, of course, was not diluted prior to filtration. In order to avoid the suspicion that the results might be due to dilution from the water contained in the wetted filter-paper, the first two drachms of the filtrate were in all cases thrown aside.

I. This specimen unfiltered showed 0.075 per cent. of albumin. Six drachms of urine were mixed with one teaspoonful of talc,¹ and then filtered. The filtrate showed less than 0.025 per cent. of albumin.

II. This specimen unfiltered showed 0.05 per cent. of albumin. Two ounces were mixed with two teaspoonfuls of talc and filtered. The filtrate showed a precipitate in the albuminometer, but too small to be measured. One ounce of this filtrate was now mixed with one teaspoonful of talc and passed through a fresh filter. This second filtrate showed a slight cloudiness with Esbach's reagent, but no precipitate. One-half ounce of this second filtrate was mixed with one-half teaspoonful of talc and put through a fresh filter. The filtrate from this gave no reaction at all with Esbach's reagent.

III. This specimen was from a case of chronic nephritis associated with valvular cardiac disease. From the history it seems probable that the renal lesion was primary. The unfiltered urine showed 0.225 per cent. of albumin. The first filtrate of two ounces of urine with two teaspoonfuls of talc reduced this to 0.15 per cent. One ounce of this filtrate was again mixed with one teaspoonful of talc and passed through a fresh filter. The amount of albumin was thereby reduced to 0.075 per cent.

IV. Another specimen was obtained from this same case a few days later. The unfiltered urine now showed 0.175 per cent. of albumin. The first filtrate showed 0.1 per cent., the second filtrate 0.05 per cent., and the third filtrate 0.025 per cent. Fresh talc, of course, was used for each filtration.

V. As the power of talc to remove albumin from the urine was by this time fully established, the following experiment was made to prove that if the quantity was constant this power varied directly almost with the amount of talc used. The original urine unfiltered showed 0.175 per cent. of albumin. When one ounce was mixed with two teaspoonfuls of talc, the filtrate showed 0.1 per cent.; when the same quantity was mixed with three teaspoonfuls of talc, the filtrate showed 0.05 per cent.; when with four teaspoonfuls, it showed 0.025 per cent.; when mixed with five teaspoonfuls of talc, the filtrate showed an amount too small to be measured in Esbach's tube. This experiment also removes the suspicion that the comparative diminution of albumin in the successive filtrations

might be due to the repeated dilutions from the thick, wetted filters used.

VI. In order to eliminate the possibility of actual dilution, this experiment was devised. A sample of urine was taken which showed when unfiltered 0.175 per cent. of albumin. Two ounces of this were then shaken for some time with three teaspoonfuls of talc. The mixture was then poured into a precipitating glass and allowed to stand for twenty-four hours. At the end of that time practically all the talc had settled to the bottom, leaving above the clear urine considerably decolorized. This was then passed through one thickness of unwetted filter-paper, in order to get rid of a little talc at the top of the fluid. The albumin was found to be reduced to a trifle less than 0.1 per cent.

VII. It might be urged that even if talc does remove albumin, these experiments do not show that it takes all out of a specimen, and there will still be left enough to respond satisfactorily to our tests. The urine used in these experiments was intentionally selected on account of the large amount of albumin contained therein, so that any loss could be easily measured. The figures furnished by Esbach's albuminometer refer only to dry albumin, and an amount equivalent to 0.2 per cent. on that instrument would make one-fifth or one-fourth of the bulk of urine when estimated in the ordinary wet way by boiling and allowing the urine to stand for a few hours in a test tube. In fact, a percentage of albumin that furnishes no appreciable deposit in Esbach's tube will yet give perfectly satisfactory and characteristic reactions with all our tests and may be of the profoundest clinical significance. The dangers of clarifying the urine by this method are most pronounced in just these cases, which are encountered every day in ordinary practice. For example, a specimen of urine on boiling showed a distinct cloud which was not dispelled on the addition of nitric acid. On contact with nitric acid it showed instantaneously a delicate white ring at the junction of the two liquids, thus indicating albumin. On contact with acetic acid it showed a white ring, indicating mucin. The quantitative analysis showed an amount of albumin too small to be measured in Esbach's tube. One ounce was filtered with one teaspoonful of talc in the usual way. The filtrate showed no cloud on boiling; the contact test with nitric acid gave a negative result, even after half an hour, and likewise the contact test with acetic acid. In order to see if simple dilution could cause this change in the reactions, the original urine was diluted one-half with plain water. All three tests then gave positive results, although a little fainter than before dilution. The contact test with nitric acid required about two minutes before the ring of albumin appeared, but then it was typical.

This loss of albumin has occurred repeatedly in my analyses, and might readily have led to the most serious mistakes. It is on this account, and not from a mere academic interest, that these experiments were undertaken. The results given prove the great danger of the method, I think conclusively.

VIII. At the suggestion of D. Granville M. White, two experiments were made to determine the influence of talc in removing sugar from the urine. The first experiment showed some reduction in the amount of sugar, but, unfortunately, my notes on this case have been lost. The second experiment showed a reduction from over 0.75 per cent. before filtration to less than 0.5 per cent. after filtration, one ounce of urine having been mixed with one teaspoonful of talc.

128 WEST FIFTY-NINTH STREET.

Surgery of the Lay Press.—"Egan was removed to Bellevue Hospital, where it was found that the tendons and two arteries had been severed and one or two nerves fractured."

¹ One rather heaping teaspoonful of purified talc or French chalk was found to weigh fifty-four grains.

THE USE OF PEROXIDE OF HYDROGEN IN DISEASES OF THE NOSE, THROAT, AND EAR.¹

By W. SCHIEPPEGKELL, A.M., M.D.,

NEW ORLEANS, LA.

VICE-PRESIDENT OF THE AMERICAN LARYNGOLOGICAL, RHINOLOGICAL, AND OTOLOGICAL SOCIETY; CHAIRMAN, SECTION ON OTOLGY, LARYNGOLOGY, AND RHINOLOGY, LOUISIANA STATE MEDICAL SOCIETY; VICE-PRESIDENT, NEW ORLEANS ELECTRIC SOCIETY, ETC.

PEROXIDE of hydrogen is one of the most useful agents which we have in the treatment of diseases of the nose, throat, and ear. Its germicidal and antiseptic properties, and its capacity for destroying pus and decaying organic matter without injurious effect on healthy tissues, render it almost indispensable in many cases. It has always been a source of surprise to me that so little reference to this valuable agent is found in the foreign periodicals.

Peroxide of hydrogen is a dioxide or double oxide of hydrogen (H_2O_2), water being simply a monoxide of hydrogen (H_2O). It derives its name "peroxide" from the fact that it is the highest oxide of hydrogen known to chemistry. It was first prepared by Thénard, about seventy years ago, and was known as "oxygenated water," a name still retained in France. A given volume of it, when decomposed, yields four hundred and seventy-five times its own volume of free oxygen. In its undiluted state it is a strong cauterant of animal tissue, and is therefore usually prepared as a two- or three-per-cent. solution, the former yielding, when decomposed, ten and the second fifteen times the volume of the liquid in gaseous form.

Peroxide of hydrogen is not toxic; in fact, it is used for internal medication, and the amount which may be taken without injurious effect is well illustrated by a case recently reported, in a course of discussion on diphtheria, by Dr. Rudolph Matas. In this case, in which Dr. Matas had occasion to prescribe it for a man suffering from asthma, the patient, from a misunderstanding of the directions, took six or eight four-ounce bottles of peroxide of hydrogen during one night, and was not only not injured by this excessive amount, but actually believed that he had been benefited.

In diseases of the nose, peroxide of hydrogen is an important therapeutic agent. In ozana a wash of a twenty-five-per-cent. solution is useful; or, after washing the nostrils with an alkaline or the normal physiological salt solution, the hydrogen peroxide, pure or mixed with an equal quantity of glycerin, may be applied locally by means of an atomizer or applicator with cotton, to remove or destroy any scabs or secretion which may be left. In this way the nostrils can be kept clean, and the offensive odor, which is one of the most unpleasant features of this disease, may be prevented. In purulent rhinitis a five-per-cent. solution, to which an alkali has been added, is useful. It is also said to be serviceable in controlling nasal and pharyngeal hemorrhage.

In membranous rhinitis, whether due to the Klebs-Loeffler bacillus or to micrococci, the spraying of the nostrils with a twenty- to fifty-per-cent. solution is indicated, and has given me excellent results. My experience in diphtheritic rhinitis with this agent has been so satisfactory that I have not deemed it necessary to use the antitoxin in these cases, as this does not seem to prevent the post-diphtheritic paralysis, which would be the only reason for my using it in diphtheritic rhinitis.

In specific necrosis in the nostrils, peroxide of hydrogen is an important agent, not only for its disinfecting properties, but also for controlling the horrible odor that is present in these cases. In diseases of the

accessory sinuses of the nose, peroxide of hydrogen is so beneficial that I use it in all cases, whether of a maxillary, frontal, ethmoidal, or sphenoidal sinus. In my opinion it cleans and disinfects the infractuositities of these cavities more effectively than any agent that we have.

In diseases of the throat, peroxide of hydrogen is used in follicular and other forms of tonsillitis, and in specific affections, and is a sheet anchor in diphtheritic processes in this region. Long before the introduction of antitoxin, I have had excellent results from hydrogen peroxide in diphtheria, and even since the use of this serum I never fail to use the peroxide as a valuable adjunct, and I believe it to have had an important bearing on the results obtained. It attacks the membrane, disinfects the parts, and has no injurious effects when swallowed, which is more than can be said of many other antiseptics used for this purpose. In a recent case of laryngeal diphtheria, to which I was called in consultation, the stridor and dyspnea were so marked that I was compelled at once to introduce an intubation tube. The tube, however, was repeatedly coughed out, and I then made use of a procedure which I had found beneficial in former cases—the injection of a seventy-five-per-cent. alkaline solution of peroxide of hydrogen directly into the larynx, by means of a laryngeal syringe. The relief given by this injection was so great that I was not compelled to intubate again, but simply to make these injections every four hours. The patient also received three injections of diphtheria antitoxin serum, which I made at intervals of twenty-four hours, and the child made a good recovery. Recently a German author called attention to the irritating effects of peroxide of hydrogen on the mucous membrane. This effect I have found in none of my cases, although this may be due to the fact that in employing this agent I make use of a small addition of bicarbonate of soda, and that I adjust the strength of the solution to the requirements of the case.

Diseases of the ear offer a good field for the use of peroxide of hydrogen. As a non-irritating antiseptic wash it is invaluable, as in the various forms of suppuration, especially when they are accompanied with a disagreeable odor. In diffuse or circumscribed inflammation of the external canal, peroxide of hydrogen is useful after an incision has been made; and in suppurative otitis media, especially in neglected cases, a five- to fifteen-per-cent. solution is of great assistance. In cases complicated by inflammation of the mastoid cells, especially in the suppurative form, the indication for peroxide of hydrogen is clear, although this does not prevent the use of iodoform, aristol, and other antiseptic agents.

In acute cases of purulent otitis media, a five-per-cent. alkaline solution should be used, as strong solutions are not necessary and may be injurious.

MEDICAL BUILDING.

Ectopic Gestation.—Dr. MacMonagle (*Southern California Practitioner*, May, 1896) names the following conditions which may be mistaken for ectopic gestation or for which it may be mistaken: 1. Uterine pregnancy. 2. Retroversion of the gravid uterus. 3. Ovarian tumors. 4. Cysts of the broad ligament; distended Fallopian tubes. 5. Fibro-myoma and fibrocystic tumors of the uterus. 6. Pelvic hamatocele. 7. Pelvic inflammatory exudations. 8. Malignant disease in the abdomen or pelvis. 9. Pregnancy in the rudimentary horn of a malformed uterus. 10. Pregnancy in a well-formed bicornute uterus. 11. Spurious pregnancy. 12. Perforation of the vermiform appendix, with rapid extravasation of fecal matter and shock.

¹ Read at the meeting of the Western Society of Eye, Ear, Throat and Nose Surgeons, April 9, 1896.

Progress of Medical Science.

The Treatment of Inoperable Malignant Tumors by the Toxins of Coley.—Dr. Henry Matagne, of Brussels, reports in the *Gazette Médicale de Liège*, May 14, 1896, a series of fourteen cases of malignant tumors treated by injections of the mixed toxins of erysipelas and bacillus prodigiosus, and states that he obtained one complete cure. The patient was a man, sixty-four years of age, of strong constitution. In January, 1895, he first noticed something abnormal in the floor of his mouth. In February he consulted a physician, who made the diagnosis of an epitheliomatous tumor and advised operative treatment, to which the patient refused to submit. He consulted several other physicians of high authority, who confirmed the diagnosis and advised operation. In the beginning of June, 1895, he consulted Dr. Matagne. The patient at that time presented a tumor consisting of three lobes occupying the floor of the mouth to the left of the frenum of the tongue, the largest lobe being about the size of a nut; the two other lobes extended one to the right side of the frenum, the other toward the base of the tongue. In the left submaxillary region there was a gland the size of a small nut, and under the chin were two other glands, respectively the size of a bean. The tumor was indurated, there was very superficial ulceration without suppuration, and there were lancinating pains radiating toward the left ear. In brief there were all the clinical signs of cancer, and all who had examined the growth agreed that it was an undoubted case of epithelioma. Histological examination of the neoplasm was not made. The fear of jeopardizing the progress of the treatment in opening a gate to secondary infections was reason for not removing a piece for examination. The treatment was begun on the 10th of June; subcutaneous injections were given in the subhyoid region, the initial dose of the toxins being five centigrams. Two hours later the temperature was 38.5° C. On the 16th of June forty centigrammes were injected into the tumor; severe rigors followed one-half hour later; the tongue was greatly swollen for two days. The highest temperature reached during the treatment was 41° C. During the whole febrile period the tumor diminished to a marked degree. This diminution continued after the cessation of the fever, and by the beginning of September no trace of the tumor remained. The second case was one of recurrent sarcoma of the neck, occurring in a woman seventy-eight years of age. The tumor was the size of an egg and located in the sterno-mastoid muscle. There was another tumor the size of a small nut in the region of the masseter, and two small, very hard glands were found underneath the chin. After the treatment had been continued for three and a half months, the injections being given every other day, the large tumor had completely disappeared. The tumor in the region of the masseter was scarcely perceptible. The glands had not entirely disappeared when the treatment was accidentally interrupted. At present, six months after the cessation of the injections, there is a slight recurrence of the trouble; the patient has been advised to renew the injections. In a third case, a recurrent sarcoma of the neck, the size of a fetal head, the patient was treated with the toxins for three months and the tumor had diminished to two-thirds its original size, when the patient, tired of the long duration of the treatment, preferred to consult a surgeon. The operation proved fatal. In a fourth case reported, a recurrent sarcoma of the arm, the injections only temporarily retarded the growth. In the fifth case, a sarcoma of the jaw,

there was no result, except a temporary arrest in the progress of the disease. Case VI. was a deeply ulcerated sarcoma of the neck, occurring in a very feeble man sixty-four years of age. The patient died after five weeks of treatment during a reaction which followed an injection of ten cubic centimetres of the toxins. The tumor had diminished a little in volume. The remaining seven cases were all of epithelioma or carcinoma and there was very little result, except in two cases; in one of these, a case of recurrent carcinoma of the breast, the injections seemed to produce an arrest in the progress of the growth, the latter remaining stationary for several months. In the other case, a cancer of the uterus, there was diminution of the pain and a decrease in the size of the tumor. The improvement lasted for four months.

Ligature of the Innominate Artery.—In the *Boston Medical and Surgical Journal* Dr. Burrell has reported a case of ligation of the innominate artery in which the patient lived one hundred and four days after operation. According to the author this case teaches: 1. That a patient with general arterio-sclerosis and an enlarged and dilated heart may be kept under ether one hour and a half, subjected to a severe operation, and recover with little shock. 2. That while ligation of the innominate artery is not of necessity fatal, yet it will always be an extraordinary operation, fraught with danger from the cutting off of an extensive area of circulation. The removal of the sterno-clavicular articulation, and such a portion of the sternum as may be necessary, makes the performance of the operation more practical and one of relative simplicity and safety. 3. That the absence of pain or marked discomfort following the operation, the complete relief of all the patient's symptoms, and his almost uneventful recovery are remarkable. 4. That the secondary hemorrhages which have occurred in almost all of the recorded cases were undoubtedly due to local sepsis, and that the recovery of this case was due to the accuracy with which it was possible to place the ligatures and to the asepsis. 5. That if the innominate is ligated at all, two ligatures are necessary, one to act as a breakwater by obstructing the constantly recurring waves of blood coming from the aorta. 6. That the collateral circulation was principally established in this case by a downward stream of blood from the right carotid and vertebral arteries into the subclavian artery. That while the fusiform aneurism had shrunk, there was very little clot above the second ligature. This would lead him in another case of fusiform aneurism in this situation to ligature the carotid, if possible the subclavian in its first part, and, if practical, the vertebral. 7. That the unique behavior of the first ligature that was applied to the innominate is perhaps the most interesting fact which we learn from this case. When the innominate artery was tied something in the wall was felt to give way. The ligature gradually cut its way through the coats of the vessel, and this was followed by an inflammation in the organization which prevented a secondary hemorrhage, and finally rested, organized and probably covered with a smooth layer of intima, inside the innominate artery. This places a new factor at our disposal as regards final disposition of the ligature.

New York, August 8, 1896.

MÉNIÈRE'S DISEASE AND ITS TREATMENT.

THE complex of symptoms which goes under the name of Ménière's disease often causes the patient a great deal of distress and the physician much anxiety, on account of the painful and obstinate nature of the symptoms. Ménière's disease has been written about to a very great extent, since Ménière himself published his original article in the *Gazette Médicale de Paris*, in 1861. A recent monograph upon the subject, by Dr. Fränkel-Hochwart, contains nearly six pages of bibliography. The result of all this research has been to establish the fact that the vertigo and other accompanying symptoms in Ménière's disease are due to an irritation of the vestibular and cochlear branches of the eighth nerve. This irritation, it has been shown, is due to very different causes. It may be a syphilitic exudate or some other inflammatory process in the internal ear, or, as is more commonly the case, a chronic inflammatory disease of the middle ear with secondary involvement of the labyrinth. Apparently there are cases of Ménière's disease also in which the condition is functional—cases in which no evidence, at least, of real organic disease can be found, and in which the convulsibility of the epileptic constitution shows itself; or cases of neurasthenia, in which the point of least resistance is the eighth nerve. The causes and the pathological changes underlying the symptoms that go by the name of "Ménière's disease" are indeed so various that it is somewhat unfortunate that a specific name has been given to the condition, since neither the periodicity of the attacks nor the progressiveness of the disorder, in fact no symptom aside from the vertigo, may be considered constant in persons who suffer from this malady. This fact is abundantly shown by a study of Hochwart's classification. He tells his readers that there are four different kinds of Ménière's disease, with some nine different subdivisions of these four classes. Thus, we have the epileptiform, due to a sudden hemorrhage into the labyrinth; the traumatic form, in which, perhaps, a fracture or some direct injury of the ear structure occurs. Then we have the progressive form, which develops on the basis of a previous ear disease. This type of Ménière's disease is subdivided in accordance with the location of the ear trouble and in accordance with its chronicity or acuteness. Ménière's disease may develop on the

basis of lesions occurring either in the external ear, on the one hand, or in degenerative diseases, involving the nucleus of the nerve, on the other. Still another form of Ménière's disease is described as occurring as the result of mechanical causes, such as washing out the ear, catheterizations, seasickness, and so on. And, finally, there are attacks of Ménière's disease which are called pseudo-attacks, and which are due to hysterical, epileptic, or migrainous neuroses.

The conclusion which one would most naturally and logically reach, from a survey of the literature on this subject, is that the term "Ménière's disease," had much better be abolished and the term "aural vertigo" be used in its place. The physician then, when a patient presented himself with a history of severe attacks of vertigo, would have to ascertain only if the vertigo were of aural origin; if so, in what part of the ear it was situated, and, finally, what was the nature of the pathological process. This is really the problem that is to be solved in every case, and it is often obscured by the physician feeling anxious to make out a picture which will correspond with so-called Ménière's disease. He should be satisfied with establishing the relationship of the symptoms to the eighth cranial nerve.

These remarks are a somewhat lengthened preliminary to the notice of a practical communication upon the subject, made by Dr. Lemarié, in the *Annales des Maladies de l'Oreille, du Larynx, du Nez, et du Pharynx*. The drugs which have been used in this disease vary, naturally, with the stage and form of the trouble, but the bromide of potassium, salicylate of sodium, the sulphate of quinine, iodide of potassium, and, finally, pilocarpine, have been most frequently recommended.

It is with regard to the efficacy of the last-named remedy that Dr. Lemarié writes. He reports the case of a man of thirty-five, who suffered most severely from attacks of the *syndrome de Ménière*. The attacks developed suddenly on the basis of a chronic middle-ear disease, involving both ears. For a week he was treated in various ways without success, the attacks coming on as usual and the continual vertigo annoying him greatly. At the end of a week, treatment with pilocarpine was begun. He used a solution of ten centigrams of nitrate of pilocarpine in ten grams of distilled water. Injections were given every day, the patient lying in bed during the time, and until after the "sweat crisis," that is to say, for about two hours. The dose at first was four milligrams of the solution, and was increased by one milligram every two days. Besides the physiological action of pilocarpine upon the saliva, the sweating, and the urine, a progressive amelioration in the state of the patient took place. Fifteen days after the beginning of treatment he was able to go about the wards, and in about fifteen days more he left the hospital, practically cured.

Rabies in Pennsylvania.—Rabies has broken out among the cows, dogs, sheep, and hogs in Path Valley, Centre County, Pa., and it is feared that the disease will become general throughout the county.

CATHETERIZATION OF THE URETERS.

SURGICAL treatment of diseases of the kidneys has become so frequent in large hospitals as to make it extremely important to diagnosticate the exact condition of the two organs as nearly as possible before the operation. Such unfortunate occurrences as removal of an only kidney, the other being congenitally absent, or extirpation of a diseased organ when its fellow happened to be in no better condition, had stimulated the ingenuity of surgeons in their search for a safe and effectual means of withdrawing urine secreted by one kidney before it entered the bladder to become mixed with that secreted by the other. By this means it was hoped that not only would knowledge be obtained of the existence of one or both kidneys, but that the amount and condition of the urine would furnish a reliable index to the condition of the respective secreting organ. Obstruction of the ureter by pressure is both difficult of application and uncertain in its result, for one cannot be assured that the flow from that side has been entirely checked. Moreover, cystitis may exist, and the urine from the other kidney on passing into the diseased viscus will then contain morphological elements which may or may not have been furnished by the kidney. This led to attempts to catheterize the ureter through a vesico-vaginal fistula, or even through an artificial opening made for that purpose. The introduction of the incandescent light, whereby cystoscopy was made practical a few years since, led to efforts at catheterization of the ureters through the bladder, and the clinical work of Casper Meyer, Kelly, and others is sufficient testimony of the success which has crowned those efforts.

The urethra being shorter and larger in women, it was to be expected that cystoscopy and catheterization of the ureters would become a practical art in them sooner than in men, and so it did. In a work recently published on the diagnostic value of ureteral catheterization¹ Casper credits Dr. James Brown, of Baltimore, with having first successfully catheterized the male urethra (June 9th, 1893), but with an instrument which was found both uncertain and liable to injure the ureter. He urges the same objections against the Nitze ureter-cystoscope. The catheter leaves the cystoscope at a definite angle, and even if one succeeds in introducing it into the mouth of the ureter, it is liable, on account of the fixity of that angle, to damage the lower ureter, whose course is more or less variable. Moreover, there is difficulty in withdrawing the cystoscope and leaving the catheter in the ureter. Casper overcomes these objections, at least in a degree, by causing the end of the catheter to leave a fenestra whose length can be increased or diminished by a slide. Moving the slide forward shortens the opening and gives the projecting end of the catheter a more acute angle, whereas retraction of the slide lengthens the opening so that the catheter assumes a greater curve and also conforms more readily to the course of the ureter when introduced. By entirely withdrawing the slide or sheath, the catheter can be lifted free from

the cystoscope and allowed to remain while the latter is withdrawn. The ureter-cystoscope has reached that degree of perfection, and its application has been made sufficiently easy in women at least, certainly to render inexcusable at the present time removal of an only kidney, or cutting down upon the healthy organ when it is known that one of the two must be diseased. But up to the present ureteral catheterization has not proven to be so innocuous as to justify indiscriminate application for the purpose either of gaining experience or of guarding the ureter against a mere possibility of injury during operations, for the longer the catheter is allowed to remain in place the more likely it is to excite inflammation or expose to infection. In man, even the introduction of a large sound without marked curve into the bladder is not a trifling procedure, and it is safe to say that if all surgeons should undertake ureteral catheterization, the number of patients not requiring, but rather being damaged by, such practice would exceed the number to whom it could be of benefit. In other words, it would seem that here, for the present, is a field for the cultivation of a specialty within a specialty.

To be of value therapeutically, catheterization of the ureters would in most cases have to be repeated a number of times, which fact of itself would indicate that in this direction its application will be more limited than in diagnosis, yet it has been resorted to for flushing the pelvis of the kidney, dilatation of ureteral stricture, dislodgment of gravel, etc., with advantage.

In ureteritis, Mann, Reynolds, Etheridge, Laphorn Smith, and others say that constitutional treatment, particularly free use of water, is more promising than local applications.

THE SURGICAL TREATMENT OF EXOPHTHALMIC GOITRE.

SINCE extirpation of the enlarged thyroid gland was first practised in 1880 for the relief of the symptoms of exophthalmic goitre the subject of this operation has been a matter of considerable discussion. Some authorities would operate in almost all if not all cases; others would be as sweeping in the limitation of surgical intervention; while still others would be governed by the urgency of the symptoms referable to the thyroid gland—as a result either of pressure or of intoxication due to failure of function. According to the latest dictum the cases most suitable for thyroidectomy are those in which psycho-neurotic symptoms predominate and which have resisted other therapeutic measures. To the not yet large number of cases operated on Berndt¹ adds two more, in one of which a perfect cure was effected, while in the other only improvement resulted.

The successful case occurred in an unmarried woman, sixty-five years old, in whom palpitation of the heart followed emotional disturbances at the age of thirty-five years. Shortly afterward a pulsatile swelling made its appearance on the left side of the

¹ "Die diagnostische Bedeutung des Katheterismus der Ureteren," von Dr. Leopold Casper. Berlin: Oscar Coblentz, 1896.

¹ Archiv für klinische Chirurgie, No. 4, 1896.

neck. Subsequently the diagnosis of exophthalmic goitre was made by a distinguished clinician, despite the absence of exophthalmos. Later in the history of the case the woman suffered from violent attacks of delirium cordis, characterized by tachycardia, with a sense of anxiety and of oppression, and followed by sweating. As time went on, symptoms of melancholia, with suicidal tendencies, made their appearance. Varied treatment had been employed at different times, but without avail. When finally operation was proposed the woman readily assented. Accordingly, the enlarged left lobe of the thyroid gland was removed, together with a nodule of considerable size that was found in the anterior mediastinum. The right lobe of the gland was not enlarged, nor was the trachea compressed or softened. Following the operation the pulse progressively diminished in frequency to the normal and the other symptoms gradually disappeared.

The second case occurred in a married woman, fifty-eight years old, in whom palpitation of the heart developed at the age of twenty-five years in the train of hard work. The patient had always been irritable. In the course of two years swelling of the neck made its appearance. The skin became pigmented and the eyes protruded. The patient complained of sleeplessness, of a sense of fear, of restlessness, of dyspnoea, and sweating. After ten years of unavailing medical treatment an operation was readily agreed to. Both lobes of the thyroid gland were enlarged, the left, however, in greater degree, but the trachea was not affected. The left lobe and a retro-sternal nodule that was found were removed, but failure of the heart necessitated premature termination of the operation. The condition of the patient was greatly improved after the operation, but death resulted a year later from pneumonia complicating influenza.

Berndt looks upon exophthalmic goitre as a reflex neurosis originating in the irritation resulting from the torsion, traction, and compression of the sympathetic nerve endings in the thyroid gland due to the morbid changes in its structure. These conditions are removed by thyroidectomy and with the removal of their cause the symptoms likewise disappear.

News of the Week.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending July 25, 1896: July 18th.—Assistant Surgeon L. Morris, detached from Indian Head proving ground, ordered home, and granted one month's leave. July 21st.—Assistant Surgeon F. C. Cook detached from treatment at the New York hospital and ordered to proceed home; Medical Director G. H. Cook detached from special duty at Philadelphia and ordered to take charge of hospital there; Medical Director D. Kindleberger, detached from duty in charge of hospital at Philadelphia, and ordered home to await orders; Medical Inspector W. G. Farwell ordered to special duty at Philadelphia attending officers.

Dr. Edward N. Brush, superintendent of the Shepard Asylum, has been elected professor of psychiatry in the Woman's Medical College of Baltimore.

The American Electro-Therapeutic Association.

—The sixth annual meeting of this association will be held on September 29 and 30 and October 1, 1896, in Allston Hall, Studio Building, on Clarendon Street, near St. James Avenue, Boston, Mass.

The American Pharmaceutical Association will hold its annual meeting in Montreal, August 12th–20th. An attendance of between seven hundred and eight hundred is looked for, and great preparations have been made for their entertainment.

Extreme Heat in the Southwest.—The temperature in Little Rock and Oklahoma during the past two weeks has exceeded that ever known there. At Little Rock, according to a recently issued bulletin of the weather bureau, the maximum temperature during the past twelve days was 102° F. on eleven days, and 104° F. on one day.

The Royal College of Surgeons.—By the election of Sir William MacCormac to the presidency of the Royal College of Surgeons, a St. Thomas Hospital man has been honored for the first time in fourteen years, since the election of Sir Spencer Wells.

Inspection of Charitable Institutions.—The New York State board of charities has appointed Dr. Stephen Smith, of this city, and Enoch V. Stoddard, of Rochester, a committee to inspect the charitable institutions of the State. This is one of the duties imposed by law upon the board.

Second Pan-American Medical Congress.—Dr. Francisco Bastillos, No. 7 Calle de Tacuba, Mexico, is the treasurer of the second Pan-American Medical Congress, to be held in the City of Mexico during the week beginning November 16th. All physicians residing in the United States and Canada who contemplate attending are requested to forward the registration fee of \$5 to him, and at the same time to notify Dr. C. A. L. Reed, of Cincinnati.

Beriberi at Philadelphia.—The Norwegian bark *Canopus*, which reached Philadelphia on July 29th from Mauritius, had on board six severe and several mild cases of beriberi. The former were detained at the quarantine hospital. The disease made its appearance as the vessel was crossing the equator.

An International Congress of Medical Ethics is the latest proposal. According to the *Scalpel* of England, a journal of the same name in Belgium proposes the institution of an International Congress of Deontology and Medical Legislation, and gives the following views as to the programme that should be adopted: "To lay down the fundamental rules of a code of honor, which shall serve as a guide to all practitioners in the multiple contingencies appertaining to a medical career; the relations that should obtain between neighbors, between strangers, between general practitioners and specialists, between the rank

and file of the profession and the staffs of hospitals, between physicians and surgeons, consultants and family attendants, beginners and veterans, men practising in watering-places and those sending patients to undergo the cure, etc."

Dr. John H. Packard has resigned from the surgical staff of the Pennsylvania Hospital, and **Dr. William Barton Hopkins** has been elected his successor.

Spinal Meningitis among Stock.—Spinal meningitis has broken out among a number of horses near Newtown Square, Pa., and five of the animals have died. The disease has been unusually prevalent among the stock in Chester County during the present summer.

Homœopathic Representation on Hospital Medical Boards.—At a special meeting of the managers of the Chester (Pa.) Hospital, on July 28th, an amendment to the by-laws admitting homœopathic physicians to the medical staff was rejected.

The Mississippi Valley Medical Association will hold its meeting at St. Paul, on September 15th, 16th, 17th, and 18th, instead of a month later, as was previously announced. The change is made in order to give the members and their families an opportunity for a tour through the Yellowstone Park. Information concerning this excursion may be obtained by addressing **Dr. C. A. Wheaton**, St. Paul, Minn.

The American Association of Obstetricians and Gynecologists will hold its ninth annual session at the Hotel Jefferson, Richmond, Va., on September 22d, 23d, and 24th. The preliminary programme contains the titles of thirty-five papers.

The Heat in Europe has been excessive thus far this summer, and has caused much suffering as well as many fatalities. Eighteen deaths are reported to have occurred at Königsberg on July 30th and 31st as the result of sunstrokes.

Obituary Notes.—**DR. WILLIAMSON**, of Greenville, Pa., was fatally injured, on July 23d, by being struck by a freight train.—**DR. JOHN DALE DILLON** was killed at Philadelphia, on July 28th, by jumping from the fourth story of his residence while temporarily insane. He was forty years old. He was graduated from Jefferson Medical College in 1877, and served for a term as resident physician in the Philadelphia Hospital.—**DR. JOSEPH M. TONER**, of Washington, died on July 31st. He was widely known not only as a physician but also as a scientist, historian, and philanthropist. He presented to Congress in 1882 a valuable collection of thirty thousand historical and medical works, and for many years he had been engaged in gathering copies of every original letter and paper of George Washington. This forms the largest collection of Washington letters ever put together. It is permanently deposited in the Congress library. **Dr. Toner** was a graduate of the Jefferson Medical College in the class of 1853.—**SIR WILLIAM ROBERT GROVE**, F.R.S., died in London, on August 2d. He was educated for the legal profession, but early turned his attention to the physical sciences, and especially

to electricity, in which he made many discoveries, being the inventor, among other things, of the battery which bears its name.—**DR. LAWRENCE B. CORTELYOU**, of Brooklyn, was instantly killed by falling from a third-story window of his house on August 5th. He had been ill for some time and was delirious at the time the accident occurred.

The National Association of Dental Faculties held its annual meeting in Saratoga, on August 1st, under the presidency of **Dr. S. H. Guilford**, of Philadelphia.

Electricity in Diabetes.—**M. d'Arsonval**, in a recent paper read before the Paris Academy of Sciences, said that he had been trying on two patients the high-frequency currents of Tesla for diabetes, and with excellent results. At the commencement of the treatment, the urine of one patient amounted to twenty-four pints a day and contained over twenty ounces of sugar. After six weeks of the current the quantity had fallen to twelve pints and the sugar to about six ounces.

The Rapacious Plumber.—An Edinburgh plumber recently sued a man for the amount of his bill, one item of which was a guinea for "medical rubbings." The customer, who had rheumatism, so admired the dexterity the plumber displayed in rubbing lead joints in the pipes that he got the man to rub his own joints.

Effective Health Measures in Texas.—A veracious Englishman, living in Texas, wrote as follows to his mother, who lives near Gloucester in England: "I have been much interested in the accounts of the small-pox in your neighborhood. In this free and enlightened country, when it broke out in a town every one was ordered to be vaccinated. Those who objected were held against a wall by one policeman, and another stood opposite with a loaded revolver while the operation was being performed. I should much like to assist in the same way at the vaccination of some of the Stroud people." The letter was printed in a local paper, and now the good people of the place are full of admiration of the way our sanitary laws are enforced.

The "Revista de Ciencias Medicas" of Havana announces in the number for June of this year that its publication must cease. The reason is, of course, the disturbed condition of the island and the dispersion of the physicians, many of the best of whom are in the Cuban army helping to win their country's freedom. The *Revista* was founded eleven years ago and has during that time done much to advance the cause of medicine in Cuba, its pages having contained many valuable contributions relating to tropical diseases. We regret exceedingly the suspension of publication of this good journal and trust that it will be only for a short time, and that the *Revista* will rise again and share in the general prosperity that must follow the triumph of the right in Cuba.

The Pottstown (Pa.) Hospital has been the recipient of \$200, bequeathed to it by the late **Lindley R. Beecher**.

Reviews and Notices.

THE STOMACH: ITS DISORDERS, AND HOW TO CURE THEM. By J. H. KELLOGG, M.D. Illustrated. Modern Medicine Publishing Company. Battle Creek, Mich. 1896.

THIS book embodies, as we copy from the writer's preface, "first, a brief sketch of the processes of digestion; then a consideration of the causes of indigestion, and their bearing upon dietetic and other habits, to which is added a description of the various symptoms present in functional diseases of the stomach, together with the means by which they may be relieved, followed by a consideration of each of the several classes of digestive disorders, and the proper dietetic and other measures necessary for their cure." While the book contains three hundred and fifty-seven printed pages, only one page is given to the subject of "Ulcer of the Stomach" (p. 276) and one to that of "Cancer" (p. 277)! Dr. Kellogg dedicated his book to his patients; he probably foresaw that but few physicians would be inclined to read it.

THE HISTOPATHOLOGY OF THE DISEASES OF THE SKIN. By DR. P. G. UNNA. Translated from the German with the Assistance of the Author by NORMAN WALKER, M.D., F.R.C.P. Ed., Assistant Physician in Dermatology to the Royal Infirmary, Edinburgh. With Double Colored Plate Containing Nineteen Illustrations and Forty-two Additional Illustrations in the Text. Edinburgh: William F. Clay. New York: MacMillan & Co. 1896.

DR. UNNA'S work was too vast and too important not to be placed at the disposal of all dermatologists and those interested in pathology who could not read it readily in the original. It must be confessed that the difficulties of mastering many of the details are by no means small, even when the language in which they are described is that most familiar to the reader. To thoroughly appreciate and understand this treatise one must be or must become familiar with the author's technical methods, and must use his stains and study, with the aid of the book, as he has studied and worked in order to write it.

The translator has undoubtedly been aided by the author's knowledge of English, which all who have heard him speak in international meetings and elsewhere know is quite extensive. The difficulties of expressing with absolute accuracy the author's views in all instances would have been insurmountable, it would seem to us, without such aid. As it is, the work is in many respects an improvement on the original text. Some alterations have been made and illustrations have been added. The translator, having worked for a considerable time in Dr. Unna's laboratory, seems to have been peculiarly fitted for the task which he has undertaken and carried to so successful an issue.

This histopathology will undoubtedly become an era marker in the study of cutaneous pathology, and while all investigators may not accept the author's views and support his claims upon every question, they must admire his energetic work and be stimulated by it to renewed efforts to make the study of the skin what it should be. The volume contains over twelve hundred pages. Each subject is introduced by a short clinical description, but, while treatment finds no place in all these pages, that which perhaps is more important, the indications for proper management, are abundant and evident to the careful reader. No organ or set of organs offers such facilities as the skin for this branch of study and those interested in the advance of science, no less than dermatologists, may congratulate themselves upon so deep a work as that of Dr. Unna and upon so attractive a translation as that which Dr. Walker offers us.

LEHREBUCH DER KINDERKRANKHEITEN FÜR AERZTE UND STUDIRENDE. By PROF. DR. ADOLF BAGINSKY, Director of the Kaiser and Kaiserin Friedrich Children's Hospital, Extraordinary Professor of Diseases of Children at the University of Berlin. Berlin: Friedrich Wreden. 1896.

THIS very well-known text-book makes its welcome appearance as a fifth edition and considerably enlarged.

The general division of the work consists of chapters describing in turn the physiological functions of the organs of circulation, respiration, digestion, and dentition, also of the

umbilicus, skin, nerves, uropoietic system, and of the special senses. Then follows the description of the phenomena of growth and its relation to weight. The chapters on feeding and general nursing are very instructive, giving all necessary details; next follows a very important chapter on how to examine a patient.

In a chapter on general therapeutics the author gives indications and contraindications for treatment by drugs, antipyretic measures, and emetics. The diseases of the newly born are quite exhaustively considered. The septic disorders of the newly born are also given in interesting detail. The chapters on general diseases include acute infectious disorders, scarlet fever, measles, röteln, varioloid, varicella, vaccine, and articles on the combined appearance of various exanthematous eruptions. In the discussion of these subjects the author has called to his aid an amount of personal experience exceptionally great, gained from the vast material at his disposition in the numerous isolated infectious buildings.

The subject of orrhoterapy is thoroughly detailed, and Baginsky lays down the fundamental principles of this new form of treatment so clearly and so positively, basing his statements on the vast amount of material under his personal supervision, that no doubt would seem to exist in his mind as to the value of his deductions.

The most modern methods of arriving at a diagnosis in all the exanthemata, together with bacteriological and histological aids, are given in detail.

The nervous disorders of children, especially those pertaining to the brain and lesions of the spinal cord, are handled in a masterly manner. The digestive disorders, the diseases of the genito-urinary tract, the diseases of the skin and those of the spinal column (orthopaedic) are given in a clear and complete manner. The more recent drugs, their doses, and a large number of prescriptions fittingly conclude this valuable book.

THE STUDENTS' MEDICAL DICTIONARY. Including all the Words and Phrases Generally Used in Medicine, with their Proper Pronunciation and Definitions, Based on Recent Medical Literature. By GEORGE M. GOULD, A.M., M.D., Author of "An Illustrated Dictionary of Medicine, Biology, and Allied Sciences," "12,000 Medical Words Pronounced and Defined," "The Meaning and the Method of Life," "Borderland Studies;" formerly Editor of "The Medical News;" President, 1893-1894. American Academy of Medicine. With Elaborate Tables of the Bacilli, Micrococci, Leucomains, Ptomains, etc.; of the Arteries, Ganglia, Muscles, and Nerves; of Weights and Measures. Analyses of the Waters of the Mineral Springs of the United States, etc., etc. Tenth Edition, Rewritten and Enlarged. Philadelphia: P. Blakiston, Son & Co. 1896.

WHEN a work has reached its tenth edition the reviewer's task is light, for he has usually but to acquiesce in the popular verdict. It is, however, sometimes interesting to see upon what the approval of the public rests and what there is in the work that has won for it a popularity so far above that of its predecessors or contemporaries. Here also, in the present instance at least, the solution of the problem is easy. The work is popular because it deserves to be; it is compact in form and not so large as to be unwieldy; the type is clear; the definitions are concise but lucid; the method of indicating the pronunciation is simple and free from the diacritical marks which call for a constant reference to a key in another part of the work; the derivations are briefly and accurately stated; and there are very few omissions of words which a student would meet in his reading. The only word, of many of recent coinage, which we have looked for but failed to find is "orrhoterapy," a term which is much to be preferred to its barbarous synonym, "serotherapy." "Opotherapy," of contemporaneous coinage, is given as a synonym of "organotherapy." But we are sorry to note that the author retains the indefensible form, "symphysiotomy," in place of the correct "symphyseotomy." He is, moreover, inconsistent in this (a reproach from which he is usually remarkably free, even in his cacography), for in "epiphyseitis," to which he gives the preference over "epiphysitis," he distinctly recognizes the epsilon in the Greek root. "Symphyseotomy" is supported by the authority of the "International" and the "Century," as well as of the Greeks themselves, who may be presumed to know their own language, and it grieves us to see a learned medical lexicogra-

pher so obstinately sinning against light. An error such as this, however fatal it may be to any claims of last appeal, nevertheless detracts but little from the value of the dictionary as a work of reference for students, and as such we can most conscientiously recommend it. To the practitioner also, while it cannot replace the author's "Illustrated Dictionary" or Foster's "Encyclopædic Dictionary," it will be indispensable in the absence of those larger works. We may add that the editor announces that this is really a new book entirely rewritten, the plates of the older editions having been destroyed.

PROCEEDINGS OF THE AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION, at the Fifty-First Annual Meeting, Held in Denver, June 11-13, 1895.

THE papers in this volume, while necessarily of interest chiefly to alienists, contain much that is instructive to the general practitioner as well as to the student of medical jurisprudence.

THE THREE ETHICAL CODES. Detroit: The Illustrated Medical Journal Company.

THIS is an interesting comparison of the three ethical codes of the American Medical Association, the American Institute of Homœopathy, and the National Eclectic Medical Society respectively. In addition this book contains the constitution and by-laws of the American Medical Association. It will be found interesting to those who are concerned in safeguarding the morals of their neighbors.

PHYSICS FOR STUDENTS OF MEDICINE. By ALFRED DANIELL, M.A., LL.B., D.Sc., F.R.S.E., Advocate and Barrister-at-Law; Examiner in Physics to the Royal College of Physicians of Edinburgh; formerly Lecturer on Physics in the School of Medicine, Edinburgh; Author of "A Text-Book of the Principles of Physics." London and New York: Macmillan & Co. 1896.

THIS is a well-arranged little work containing all the essentials of physics for the student of medicine or the practitioner. Indeed it contains much more than medical students, in this country at least, are ordinarily expected to know, except as regards optics and perhaps electricity. The subjects are presented in a manner that renders them intelligible. The book would be specially useful to one who wished to refresh his knowledge of physics, and to learn what advances or changes in theories had been made since his college days.

STATISTICA SANITARIA DELL' ARMATA PER GLI ANNI 1893 e 1894. Roma: G. Bertero. 1896.

THIS is a collection of sanitary statistics of the Italian navy for the two years mentioned.

ANTROPOMETRIA MILITARE. Incaricato della Direzione de Lavori, DR. RIDOLFO LIVI, Capitano Medico. Parte I. Roma: Il Giornale Medico del Regio Esercito. 1896.

THIS is Part I. of a series of statistics concerning anthropometry based upon the sanitary reports of an Italian Army for the year 1859-63. The two volumes in this part deal with anthropological and ethnological data, one being made up of a number of atlases of the anthropological geography of Italy.

BURDETT'S HOSPITALS AND CHARITIES, 1896, Being the Year-Book of Philanthropy. By HENRY C. BURDETT. London: The Scientific Press; New York: Charles C. Scribner's Sons; Boston and Chicago: D. C. Heath & Co.

THIS book of eight hundred and fifty-six closely printed pages contains an enormous amount of information concerning the hospitals and charitable institutions of the English-speaking world, of this country as well as of Great Britain and the colonies. The information regarding institutions in the United States is not so complete as we could wish, but the fault lies with the officers of these institutions, and not with Mr. Burdett, whose requests for information in many cases did not even meet with the courtesy of a reply. We regret this, for if we must suffer from a glut of charitable institutions we ought at least to be able to brag of their number. In addition to the statistical information a considerable portion of the book is devoted to a discussion of topics bearing upon hospital management and the use and abuse of charities. No one interested in charitable institutions and their management can dispense with this invaluable annual.

THE ANATOMY OF THE HUMAN HEAD AND NECK. Graphically Illustrated by Means of Superimposed Plates. With Descriptive Text by DR. SCHMIDT. English Edition by WILLIAM S. FURNEAUX. Author of "Animal Physiology," "The Outdoor World," etc. New York: Thomas Whittaker.

WHITTAKER'S ANATOMICAL MODEL. A Pictorial Representation of the Human Frame and Its Organs. With Descriptive Text by DR. SCHMIDT. English Edition by WILLIAM S. FURNEAUX, Author of "Animal Physiology," "The Outdoor World," etc. Illustrated. New York: Thomas Whittaker.

THESE are two sets of superimposed plates representing sagittal sections at various levels of the head and body, which show very clearly and accurately the relative position of the internal organs and structures. While intended primarily for lay instruction, they ought to prove of service to the student in giving him his first notions of topographical anatomy, and might also be useful to the physician who wished to make clear some point to an intelligent patient.

PHILADELPHIA HOSPITAL REPORTS. Volume III. Edited by GEORGE E. DESCHWEINTZ, A.M., M.D., Member of the Ophthalmic Staff. Philadelphia: Printed by Maurice H. Power. 1896.

MEDICAL AND SURGICAL REPORTS OF THE BOSTON CITY HOSPITAL. Seventh Series. Edited by GEORGE B. SHATTUCK, M.D., W. T. COUNCILMAN, M.D., and HERBERT L. BURRELL, M.D. Boston: Published by the Trustees. 1896.

THESE two reports of two of the leading hospitals in the country contain a number of essays and clinical reports of more than usual interest.

A TREATISE ON APPENDICITIS. By JOHN B. DEAVER, M.D., Surgeon to the German Hospital, Philadelphia. Containing 32 Full-Page Plates and Other Illustrations. Philadelphia: P. Blakiston, Son & Co. 1896.

DR. DEAVER'S work is a timely and valuable contribution to the literature of appendicitis and will be hailed by those who would consign the entire management of the disease to the surgeon as a powerful argument for their side. The author is uncompromisingly in favor of the knife and holds in common with many of his surgical brethren whose lot it seldom is to see the mild and self-healing cases of this disease, that appendicitis should invariably be treated by early operation. It is perhaps for the same reason that the author makes no mention of rheumatism as an etiological factor. The disease is for him one which laughs at treatment, and the only way of removing it is to remove the affected organ. If for any reason resort must be had to non-operative measures, Dr. Deaver gives the preference to laxatives over opium. The work is profusely illustrated with plates, mostly colored. As a rule, the pictures are faithful as regards outlines, but they are too brilliantly colored. The book is one which ought to, and doubtless will, take rank as one of the best treatises in English on appendicitis from a surgical standpoint.

QUAIN'S ELEMENTS OF ANATOMY. Edited by EDWARD ALBERT SCHÄFER, F.R.S., Professor of Physiology and Histology in University College, London, and GEORGE DANCER THANE, Professor of Anatomy in University College, London. Appendix. Tenth Edition. London, New York, and Bombay: Longmans, Green & Co. 1896.

THE appendix to this new edition of "Quain's Anatomy" is devoted to superficial and regional anatomy, and is written by Profs. G. D. Thane and R. J. Godlee. The illustrations, many of which are colored, are twenty-nine in number. As an evidence of the vast amount of information condensed in these sixty-six pages of text, we find an index nearly ten pages in length.

TRANSACTIONS OF THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION. Volume VIII. Published by the Association. 1896.

THIS is the report of the eighth session of the association, held at Washington, November 12, 13, and 14, 1895. Each succeeding volume of these transactions adds to the high repute enjoyed by this society.

TRANSACTIONS OF THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS. Volume VIII. Philadelphia: William J. Dornan. 1896.

THIS is the report of the eighth annual meeting, held in Chicago, September 24, 25, and 26, 1895, under the presidency of Dr. J. H. Carstens. The book contains the usual number of papers on various subjects belonging to the branches noted in the title of the association.

THE NATIONAL FORMULARY OF UNOFFICIAL PREPARATIONS. Revised Edition. Published by the American Pharmaceutical Association. 1896.

IN this new edition of the "Formulary" the metric system has been adopted in order to make it conform to the last edition of the United States Pharmacopœia. The committee of revision of this edition was composed of Messrs. C. Lewis Diehl, A. B. Stevens, C. T. P. Fennel, and Charles Caspari, Jr. They have done their work well.

HEMORRHOIDS AND OTHER NON-MALIGNANT RECTAL DISEASES: DIAGNOSIS AND TREATMENT. By W. P. AGNEW, M.D. Third Edition. San Francisco: Pacific Press Publishing Company. 1896.

THE author justifies the title of his book by entering at once upon the subject of hemorrhoids, which occupies about seventy-five of the two hundred pages. He is an earnest believer in the treatment of this painful affection by carbolic-acid injections, which he looks upon as all-sufficient for its cure. Following the chapter on hemorrhoids is one upon rectal examination, and after this come the various non-cancerous affections of the rectum. The book is written in a conversational style which makes it easy of comprehension and holds the reader's attention. The illustrations are rather crude.

STERILITY. By ROBERT BELL, M.D., F.F.P.S.G., Senior Physician to the Glasgow Hospital for Diseases Peculiar to Women.

THE author of this little book holds that the most potent if not the sole cause of sterility is endometritis, and consequently the treatment of sterility is that of the uterine disease. The writer states his case clearly, and his book possesses the interest which always attaches to the straightforward expression of an honest opinion, even when this opinion cannot be acquiesced in by the reader.

HANDATLAS DER ANATOMIE DES MENSCHEN in 750 theils farbigen Abbildungen mit Text. Mit Unterstützung von WILHELM HIS, Professor der Anatomie an der Universität Leipzig, bearbeitet von WERNER SPALTEHOLZ, ao. Professor an der Universität Leipzig und Custos der anatomischen Sammlungen. Leipzig: S. Hirzel. 1896.

THIS is the second part of the first volume of a very handsome anatomical atlas. It contains forty-four plates of the joints and a few representing sections of bones made to show their structure, accompanied by descriptive text. The book is a valuable addition to anatomical literature.

TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK, for the year 1896. Published by the Society. 1896.

THIS volume contains forty-two papers and three addresses presented at the ninetieth annual meeting of the New York State Medical Society, held at Albany, January 28, 29, and 30, 1896, under the presidency of Dr. Roswell Park, of Buffalo.

IN SICKNESS AND IN HEALTH. A Manual of Domestic Medicine and Surgery, Hygiene, Dietetics, and Nursing. Dealing in a Practical Way with the Problems Relating to the Maintenance of Health, the Prevention and Treatment of Disease, and the Most Effective Aid in Emergencies. Edited by J. WEST ROOSEVELT, M.D. New York: D. Appleton & Co. 1896.

IN considering this, in many respects, praiseworthy work, one question recurs most insistently to the mind of the reviewer—a question that asks itself in reference to so many of this species—to what class of the community is it addressed? Turning to the publishers' note we find that it claims to be "a book for household use," addressed to "the unprofessional man and woman." This is a modest claim,

which by no means does justice to the composite nature of a work the first part of which is occupied by a great mass of purely technical matter on anatomy, physiology, psychology, etc. Such information as that "regurgitation into the auricle is prevented by the mitral valve" or that "the organ of Corti is a complex mechanism resting upon one wall of the cochlear canal, the basilar membrane, and extending from the base to the apex of the cochlea," may be the matter-of-course property of every medical student in the land, but surely it is a stumbling-block even to the trained nurse, and to the laity it is foolishness. Then again, while the colored frontispiece of a trained nurse of somewhat appetizing aspect may be in order as an object lesson, there can hardly exist any ordinary citizen so greedy of useless knowledge as to waste time over diagrams of retinal sections and magnified blood corpuscles, or colored plates of anthrax bacillus and the spirillum of Asiatic cholera. As a matter of fact, people in general are coldly indifferent to the shape and size of microbes, or to the theory of germ plasm, while, on the other hand, they love to be reminded that crumbs should not be allowed to accumulate under a helpless invalid and to be admonished to ventilate sick-rooms at night.

Passing on, therefore, to that portion of the book devoted to practical matters, much may be said for its utilitarian value. The chapter on "Hygiene" may be especially noted for its satisfactory covering of much ground in small space, while those on "Physical Training" and the "Care of the Sick" may almost be called conclusive from the non-professional point of view. They possess the unusual virtue of telling those things which should be told, erring, if at all, in the direction of too minute particularization which would seem occasionally to underrate the possible intelligence of the amateur. We note, for instance, in the excellent paragraph on lifting and handling, an admonition not to stick the nails into the patient, followed by the somewhat superfluous comment that "this causes pain and irritation." But small errors of commission may be lightly held in a work where sins of omission are conspicuous by their absence, and were this the only fault we could conscientiously advise the physician to recommend the book to the families under his care. As a rule, the work is fairly free from injudicious prescriptions, yet we cannot approve of suggestions, like that on page 836, that "morphine may also be used in similar doses for sleeplessness," even though it is tempered by the caution that other and less harmful remedies should invariably be tried first. However, if there must be works on domestic medicine, this is perhaps as good as any—it is certainly the latest.

The book is well printed and well bound, the illustrations are interpretative of the text, and the whole is completed by an excellent index.

Changes in the Spinal Cord after Amputation of Extremities.—Dr. Grigoriew investigated two cases of amputation of the arm, two of amputation of the thigh, and one of amputation of the leg. The period elapsing between operation and death varied from twenty years to one year. The results of his investigations agree with those of the greater number of authorities, and are collected by the author in the following summary (*The British Medical Journal*). In all cases excepting that in which one year elapsed before death, deviations from the normal appearance of the cord were noticed; in all cases they were analogous, affected the corresponding portions of the cord, and consisted in a simple atrophy of certain portions of the gray and white substance, differing in the cases only by the degree of development. The simple atrophy of the nervous elements of the cord was greater as the period elapsing between amputation and death was greater, less as it was less; while in the case in which the period was only one year atrophy was completely wanting. With reference to the relative time before the separate paths and portions of the cord became degenerated, the author found his cases in agreement with those of other authors, and with those obtained by experiment on animals, namely, that the atrophic phenomena appear earlier and are more marked in the sensory than the motor areas of the cord.

Society Reports.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 8, 1896.

JOHN SLADE ELV, M.D., PRESIDENT.

Malposition of the Kidney.—DR. G. A. TUTTLE presented a kidney which had been situated in the hollow of the sacrum. The renal artery was given off close to the origin of the sacral media artery. This condition, the speaker said, was not extremely uncommon. In rare instances it had been known to interfere with labor. An abscess of the kidney occurring in this abnormal situation would render the diagnosis obscure.

Cystic Kidney.—Dr. Tuttle exhibited a kidney which had been removed from a man forty years of age, who had been brought to the hospital in uræmic coma. At autopsy, the kidney had been found in a state of advanced cystic degeneration. There was practically no kidney tissue remaining. Such kidneys are always bilateral. The principal symptoms in these cases are those of Bright's disease—recurrent attacks of hæmaturia and albuminuria—and the patients always die in uræmic coma. These cystic kidneys are found sometimes enormously developed in the fœtus. Virchow had advanced the theory that this cystic condition in the fœtus was due to imperforate uriniferous tubules.

Tumors of the Kidney.—Dr. Tuttle presented several microscopical specimens of tumors of the kidney. He said that during the last five years, in the pathological laboratory of the Presbyterian Hospital which received pathological material from that hospital and also from St. Luke's Hospital, there had been only ten specimens of primary new growths of the kidney. Six of these had been obtained by autopsy, and five out of the six had been discovered accidentally, having existed without symptoms during life. There was one tumor, a very large metastatic growth, which could not be treated by operation, which caused the death of the patient. Of the remaining four specimens removed by operation, three were from the surgical service of the hospital and one from an outside surgeon. The growths were from one-fourth to one inch in diameter in most instances and situated in the cortex of the kidney. Dr. Tuttle said that the exact origin and classification of primary tumors of the kidney had been a matter of much uncertainty. It was conceivable that tumors might originate in the epithelium of the pelvis, or in the tubules, or the connective tissue between the tubules, or in the blood-vessels. The structure of five of the tumors was as follows: (1) A pure lipoma, one inch in diameter, projecting above the surface of the kidney beneath the capsule. (2) A minute myoma composed of smooth muscle and some small-round cells. (3) A small papillary adenoma consisting of a small cavity lined with cuboidal epithelium. (4 and 5) Two alveolar adenomata consisting of rounded and oval spaces filled with cells resembling gland epithelium, and some of these spaces presenting a distinct lumen. In places these tumors bore a slight resemblance to the tissue of the suprarenal capsule.

In Virchow's *Archiv* was an article on the so-called lipomata of the kidney, in which it was stated that they were not rarely found accidentally at autopsy. The description corresponded with that of adenomata just given. The author considered them to be portions of suprarenal capsule which had become enclosed in the kidney during foetal life. The kidney at this period was more or less lobulated, and

it was possible that portions could be caught in these clefts. In about one thousand autopsies at the Presbyterian Hospital, one case was recorded in which a small fragment of suprarenal tissue was easily recognized under the capsule of the kidney. Under the microscope, in one portion, it was separated from the tubules by a delicate connective-tissue capsule, and in another portion the two tissues had no dividing line. These fragments had been found in many other situations, e.g., in the broad ligament, and in and about the testicles. The speaker said that it was very probable that these nodules did occasionally originate in this way from closed portions of the suprarenal tissue.

Sarcoma of the Kidney.—Dr. Tuttle then presented specimens removed from a man forty-two years of age, who had had for the first time a slight hæmaturia shortly before entering the hospital. The next day there had been difficulty in passing urine, and then pain in the left lumbar region, radiating down to the left testicle and glans penis. After about five days the urine had again become clear and the pain had ceased. About two weeks later there had been a second attack of hæmaturia. A third attack with pain occurred just before his admission. About six weeks before this a tumor had begun to grow from the right shoulder. Examination showed a large hard mass in the left kidney, and the diagnosis was made of renal tumor with metastasis. At the autopsy there was found a dense mass, weighing two pounds eleven ounces, and extending from the spleen to the brim of the pelvis, and from the floating ribs to the right border of the vertebral column on the left side. It was a new growth involving the left kidney. There were numerous metastatic deposits in the liver and lung, varying from one-fourth of an inch to two inches in diameter. Microscopical examination of these tumors showed a stroma of dense connective tissue, forming spaces subdivided into small rounded alveoli. Some of these alveoli were completely filled with cells resembling epithelium, but the larger number showed the opening between the cells filled with blood. It was possible that a hemorrhage into a carcinoma might produce some of these appearances, but, considering that all the metastases showed the same structure, one would be justified in calling this a sarcoma developed from the blood-vessels of the kidney. The tumor and metastatic growths were exhibited under the microscope.

Papilloma of the Kidney.—The next tumor presented was from a male, thirty-six years of age, who had always enjoyed good health with the exception of rather frequent and severe headaches. One week before coming under observation, the urine had been noticed to be of a bright red color from the admixture of blood. There was no pain or ill health. Cystoscopic examination was made with almost negative results on account of the hemorrhage. The blood seemed to come from a point close to the neck of the bladder. Suprapubic cystotomy was then performed. The bladder wall appeared normal except for a small ulcer at the fundus. Blood was seen to issue from the left ureter. No enlargement or tenderness of the left kidney could be detected. The left kidney was removed, but the patient succumbed to the operation. The organ was moderately enlarged, and contained a number of large cystic cavities into which projected an abundance of papillary growths. The trabecular tissue was in part like dense renal tissue, and in part soft and gray. Under the microscope there were long delicate filaments of connective tissue covered with epithelium which closely resembled epithelium of the pelvis of the kidney. The appearance of the tumor seemed to indicate that it started in the pelvis of the kidney.

Endotheliomata (?) of the Kidney.—Dr. Tuttle said that the most interesting specimens were two tumors, one of them brought to the hospital by Dr. Brown from a case reported in the *Boston Medical and Surgical Journal*, of April 18, 1895, by Dr. W. M. Swift, of New Bedford. The patient, a man, forty-seven years of age, after suffering for a short time with night sweats, noticed a tumor in the right side of the abdomen. When examined a few months later he complained of pain in the right groin, a dragging sensation in the testicles, frequent and scanty micturition. A tumor, the size of a small cocoon, was found in the region of the right kidney. It was slightly movable and somewhat tender to pressure. The urine was normal in quantity. The tumor was removed by operation and recovery was perfect. It was situated at the lower end of the kidney and was completely encapsulated. It had apparently developed from the lower and outer part. The minute structure was the same as in the next tumor to be described, which had been removed at St. Luke's Hospital by Dr. Bangs in March, 1895. The tumor consisted of a number of nodules scattered through the kidney. The capsule was extremely vascular. Microscopical examination showed a mass of rather large cells, supported by slight, irregularly branching trabeculae, forming in places fairly complete elongated alveolar spaces, while in other places there was no alveolar arrangement. The trabeculae consisted of minute blood-vessels. In some places small areas of blood were seen surrounded by a very delicate but distinct limiting membrane. The tumor cells were rounded or polygonal with a sharply defined outline. For the most part the cell protoplasm was homogeneous and did not stain well with eosin. The nuclei were of medium size and stained well with hæmatoxylin. The character of these tumors was still doubtful. Similar tumors had been described as carcinomata, or adenomata from the proper cells of the kidney tubules, and as endotheliomata developing from the endothelium of the perivascular lymph spaces. From the great vascularity of these tumors and the relation of the cells to the blood-vessels and the connective-tissue trabeculae, the speaker said it seemed to him that they were more probably developed from the endothelium of the lymph tissue, as recently described by Hildebrandt. The cells of the suprarenal capsule were very liable to undergo fatty degeneration and then would closely resemble the structure found in these tumors, with the exception of the great vascularity. Microscopical sections of these tumors were then exhibited.

THE PRESIDENT said that he could not bring himself to believe that the last specimens were endotheliomata. He was about to present a specimen in which the adenomatous type was very clearly shown.

DR. GEORGE P. BIGGS said that in a specimen recently brought to him by Dr. Alexander for examination there was an encapsulated tumor, about as large as a medium-sized orange, projecting out a considerable distance from the kidney. The microscopical structure of this tumor was quite similar to that shown in the sections of the last tumors exhibited. In some places there was a perfectly regular adenomatous arrangement, and he looked upon his specimen as one of alveolar adenoma.

A Typical Adenoma of the Kidney.—DR. F. TILDEN BROWN presented microscopical specimens of what appeared to be a typical adenoma of the kidney. The growth had been removed from a woman, sixty-two years of age, under the care of Dr. Kammerer. It had existed for eight years. On examination it was found to be about the size of a child's head, very movable, so that there was some doubt as to its being a neoplasm of the kidney. It was not particularly vas-

cular, and was made up wholly of new growth with the exception of a little kidney tissue. The patient recovered well from the operation, but died after an attack of hemiplegia some two or three weeks later. No autopsy was obtained.

Adenoma (?) of the Kidney.—DR. J. S. ELY presented a small portion of a tumor of the kidney, together with microscopical sections of the same. In structure it seemed to him very much like the last two cases presented by Dr. Tuttle. The tumor occupied the upper portion of the kidney, pushing the remainder of this organ downward and inward. It was very distinctly encapsulated and lobulated. The centre of the tumor showed an extensive area of degeneration, but the nature of this degeneration could not be determined. The whole tumor was soft and contained much blood. There was no clinical history.

The speaker said that the most recent and complete article on this subject was by Lubarsch in Virchow's *Archiv* for 1894. He endeavored to prove that they were of suprarenal origin, and he had collected twenty-nine similar cases, in all of which careful microscopical examination had been made. In his opinion they had all developed from inclusions of the suprarenal capsule. The structure was as follows: A fine connective-tissue reticulum, consisting almost entirely of a slight adventitia of blood-vessels; on one side slight endothelial lining and on the other side large cells, for the most part columnar in shape, with rounded ends; very clear protoplasm: rather large, distinctly staining, oval nuclei, and a rather loose intranuclear network. The whole arrangement was distinctly alveolar, and the disposition of the clear, large-bodied cells was in most cases around a distinct lumen. The presence of the blood in these lumina had evidently suggested to Lubarsch that these were angio-sarcomata, but it seemed to the speaker that this could be just as well explained by supposing that it was the result of hemorrhage. Regarding the question whether those growths originated from suprarenal inclusions or were adenomata of the kidney, this observer stated that the points in favor of suprarenal origin were: (1) The clear protoplasm of the cells, which distinctly resembled the protoplasm of the suprarenal body and which was like the granulations found in the cells of the tubular epithelium; and (2) the presence of glycogen in the cell bodies and in the lumina. This, the speaker said, he had found in his specimen. Lubarsch had examined twelve tumors of the kidney and in none of these had he been able to find glycogen. Yet he cited another observer as authority for the statement that the suprarenal body frequently showed the existence of glycogen. The distinct acinus arrangement and the nature of the nuclei of the cells, resembling as they did epithelial cells, would lead him to class this tumor as an adenoma or adeno-carcinoma rather than an endothelioma, although he would admit the possibility of its being an endothelioma originating from the lymphatics. So far as he knew, glycogen was found in secreting cells—epithelial cells—and this offered an obstacle to the theory mentioned. He had on a number of occasions distinctly seen glycogen in the tubular epithelium in cases of Bright's disease—at least the reactions which are supposed to be characteristic of glycogen were readily obtained. It should be stated, however, that this glycogen is not very soluble in water. With iodine it readily stains a deep mahogany-brown, and is digested and made to disappear under the influence of the ferment of saliva. Singularly enough, after treatment with iodine, the glycogen becomes soluble in water, so that the subsequent manipulations of a specimen so treated must be carried on without contact with water.

Dr. Ely said that the difficulty was to define just

what is an endothelial cell. Anatomists were inclined now to make no distinction between epithelial and endothelial cells. Personally, he had seen only what appeared to be undoubted endotheliomata in connection with the pleura and dura mater of the brain. In these cases there appeared to be a definite endothelial structure, and the cells, when teased out, were flat or irregularly shaped, with large nuclei with a loose open reticulum—a distinct endothelial arrangement. He did not think too much stress should be laid upon the shape and size of cells: one should depend rather upon the relation of the cells to the stroma than upon the cells themselves, for pressure alters greatly the shape of cells. It was well known that the cell body might differ very materially in different conditions of degeneration.

The society then went into executive session.

Clinical Department.

REPORT OF A CASE OF APEX CATARRH SIMULATING NASAL TROUBLE.¹

By HOWARD S. STRAIGHT, M.D.,

CLEVELAND, O.

JUNE 11, 1894, a young woman, aged twenty-two years, consulted me as to a nasal difficulty. Until within a short time she had never had any trouble with her nose or throat. For a few weeks she had been troubled with stuffiness in the nose and an inability to breathe through her nose continuously. From a careful inquiry as to her history, little of importance could be obtained. Her pulse and temperature were normal. She insisted that she felt as well as usual, that she had not noticed any diminution of strength or loss of appetite, and scouted the idea that there was anything in her case except the nasal difficulty. She admitted finally that maybe she was a little tired out, but said that she had been working unusually hard in school for the last eight months. While I was suspicious that possibly some constitutional condition might be present, I could not find any symptom that justified my suspicions.

Her complexion seemed to me to be a little sallow, and whether she was slightly anæmic was a question I could not decide. The patient's own belief that it was useless to consider anything except the nasal condition also assisted in quieting my suspicions that there was a possible catarrhal condition of the apex of one or both lungs. I felt certain that an examination of the chest would be looked upon as unnecessary, that it might needlessly alarm the patient, nor could I detect anything in the case to justify a suspicion I always entertain in throat, nose, and ear cases, in patients over ten and under forty years of age. If I had not waited until a later date for an examination of the chest, my error in treating the case might have been avoided. An examination of the upper air passages revealed in the nose a longitudinal deviation of the septum on the right side and a hypertrophy of the left lower turbinate. Having concluded I had a local condition only to deal with, the hypertrophy was cauterized, the patient was given an alkaline wash, and directed to return in three days. Upon her return she seemed to have been more affected than ordinarily as a result of the cauterization. Her pulse was about 90, and her temperature 100° F. While it is not at all unusual to observe such symptoms after any intranasal operation, in my experience a patient with an apex

catarrh is much more apt to present such symptoms than a patient in whom no such condition exists. Still being somewhat suspicious as to the constitutional condition, I gave the patient a prescription of benzosol.

Four days later she returned. Her temperature and pulse were normal, and she seemed as well as at her first visit. These observations deceived me more completely than before. The constitutional treatment was discontinued and the case thereafter treated from the local standpoint only.

The return of the temperature to the normal within four days can be explained only by remembering that the patient had a normal temperature before any local interference. She had a catarrhal process at the left apex at the time of coming under observation, as later developments proved, but, contrary to rule, she had no fever. As a rule, in spite of any treatment, the slight elevation of the evening temperature will persist for weeks in such cases. The deviation was removed from the right side of the septum, and after keeping her under observation for about five weeks—until July 13, 1894—she was discharged as cured.

September 18, 1894, two months after being discharged and three months from the time she first came under observation, she returned. She had been in the country on a vacation. She had not felt well for a number of weeks. She had had a poor appetite, had been nervous, had slept badly, had lost ten pounds of flesh, was sallow and anæmic, had a coated tongue, a temperature of 101° F., and a pulse of 108 in the morning. An examination of her chest revealed at the left apex slight flattening in the left subclavicular region. There was tenderness on percussion in the second interspace next to the sternum, no change in pitch on percussion. Transference of heart sounds, cogwheeled breathing, and slightly shortened inspiration were apparent on auscultation. The following diagnosis was made:

A well-marked simple catarrhal process at the left apex, or a condition of disturbance of function of the mucous membranes of the body, the gastro-intestinal being in the majority of such cases the one of which greatest complaint is made—a condition, however, in which some one or all of the physical signs found in the case reported may be detected at the apices of the lungs, and one which is of much greater importance than a simple unassociated disturbance of the gastro-intestinal mucous membrane, for which the disease called apex catarrh is often mistaken.

My belief is that at her first visit to me in June the patient had a slight developing catarrh at the left apex. This belief is not founded upon this one case. Over and over again have I had a similar experience, although in no case has my experience been as humiliating as in this one. I have recently discharged a patient after four months' constitutional treatment whom I treated altogether locally for the first four weeks she was under my care, and I realized the need of constitutional treatment in the case only after finding marked transference of the heart sounds at the left apex. These experiences have not occurred to me because of carelessness. The possibility of such a condition is considered in the case of every patient under forty years of age and over ten.

I am not qualified to speak as to the occurrence of the condition mentioned in other localities, but in Cleveland apex catarrh—a disturbance of the functions of all the mucous membranes of the body, the disordered functions of the gastro-intestinal mucous membrane often being the one of which the patient makes most complaint, but a condition in which certain definite physical signs at one or both apices of the lungs can be detected—is of very frequent occurrence: and after years of observation and large opportunity in the study of the diseases of the ear and upper air pas-

¹ Read before the American Laryngological, Rhinological, and Otological Society at its second annual meeting in New York City, April 18, 1896.

sages, I believe that this condition—call it what you will—is in Cleveland more important to the throat specialist than all other constitutional conditions combined. The question arises as to whether the subsequent ill health and loss of flesh were not due to the local treatment. It is most natural for the patient to hold this opinion. It is not at all uncommon for patients in perfect constitutional condition to feel depressed for a short time after intranasal treatment and even to lose flesh, but they quickly recuperate and take no such course as the one reported.

If this patient had presented herself to a general practitioner instead of a throat specialist, and he, knowing nothing of the nasal condition, had detected the condition of her left apex and treated her constitutionally with as much success as attended my efforts, when she returned to the city in September what would have been the result as to the local lesion? She probably would have been relieved so much that the local lesion would have caused no more trouble than had been experienced when she was perfectly well. You remember she had had no trouble with her nose until within a few months. The local treatment certainly did no harm, for constitutional treatment would not have remedied or relieved the hypertrophy of the mucous membrane of the left lower turbinated or a deviation of the septum; but the overlooking of the constitutional condition was an error indeed—such an error as brings specialism into merited disrepute. The oversight was made by one fully alive to the importance of looking beyond the local lesion, and one who was a general practitioner for years.

This experience has simply added weight to an opinion long since formed, that the specialist should always seek an explanation of local symptoms in a patient's constitutional condition. It may not always be easy or possible to decide which factor is the more important in a given case. The necessity of studying the patients as a whole is understood by every one. The general practitioner errs ordinarily in paying too little attention to local conditions. The specialist, on the other hand, errs too often in paying too great attention to local conditions. The golden mean is the position all are striving to attain. When the general practitioner more carefully studies the importance and possible influence of local conditions, the specialist will no longer complain of lack of support in his work; and when the specialist more carefully considers the possibilities and bearings of constitutional conditions, he will command more respect and support from the conservative, sensible general practitioner.

Little may have been proven in this report. It is necessarily fragmentary because of the length of time already occupied in the discussion of the case. I know no way of absolutely proving one's opinion in a medical case. The experience added weight to a lesson learned often before and often since.

While the opinion expressed in the report may be such as is not generally held by the profession, it is certainly worthy of consideration, for I am positive that my success in the treatment of the ear and upper air passages has been much greater and much more satisfactory since I properly appreciated that which was the key to the situation in the case reported, and which I have called apex catarrh.

APRIL 13, 1896.

Intestinal Perforation in Typhoid.—There is no complication of enteric fever more dreaded by the physician than perforation. It occurs in about two per cent. of all cases. Its most frequent causes are improper diet, distention of the bowel from any cause, or too early and sudden movements of the patient.—WIGGIN.

THE STRENGTHENING AND STERILIZATION OF CATGUT.

By DONALD B. PRITCHARD, M.D.,

WINONA, MINN.

HAVING seen in some sample journal a two or three line item recommending the preparation of aseptic catgut by first treating it with formalin and then boiling, I thought it worth while to try it. Being much pleased with the result, it would seem but proper that I should bring it more generally to the notice of the profession. After trying various strengths of the formalin, I find the twenty per cent. to be the most satisfactory, leaving the gut immersed in it for three and one-half hours. It should then be at once transferred to boiling water for fifteen minutes or longer, if one so desires, when it will be found in excellent condition. Raw gut that bears a weight of thirty pounds will after the formalin treatment lift twenty-six pounds, and boiling it for fifteen minutes does not weaken it. It is curious that the gut which has been prepared for several weeks seems to become nearly as strong as the original raw article.

If one wishes to boil it on spools, care should be taken to wind it very loosely, as it swells and contracts during boiling and might easily be broken. The better plan is to prepare it before winding on spools; then with aseptic hands it can be made ready for storing away in alcohol for future use.

One day I left some gut in the formalin for eight hours and found it rotten. It would lift but six pounds. After boiling for fifteen minutes I was surprised to find that it would bear a weight of sixteen pounds before breaking. So far as I can ascertain, twelve minutes is the longest time that bacteriologists consider that anthrax spores can resist boiling water. Surely, then, fifteen minutes' boiling ought in every instance to render catgut sterile.

DISINFECTION OF THE HANDS DURING LABOR.

By HARVEY B. BASHORE, M.D.,

WEST FAIRVIEW, PA.

THERE is always a danger that valuable methods in science and art may be neglected on account of their complexity; and this seems to me to be just about the position of hand disinfection during labor. The elaborate methods which are advised in certain quarters will perhaps do well enough in a maternity hospital, but most women are confined at their homes, and what we want is a method for the practitioner which is both effective and at the same time as simple as possible.

It is generally conceded, I believe, that the streptococci, staphylococci, and Escherich's colon bacilli are about the only germs we have to fear during labor. Staphylococci and streptococci are non-spore-bearing, and consequently are easily destroyed. Robert Koch is the authority for the statement that a solution of bichloride, 1 to 1,000, destroys these organisms in a few moments. Escherich's bacillus likewise does not form spores, and is killed by the same solution in a short time, unless the germs are in feces or an albuminoid mixture (Sternberg).

In the light of these bacteriological facts, we can build a method for protection against these germs. This method, which has been widely used, is practically Fürbringer's method of hand disinfection for surgical operations:

(1) We wash our hands for several minutes in soap and water—bichloride, if you wish.

(2) They are then thoroughly rubbed for one minute with several ounces of ether.

(3) They are then scrubbed with a nailbrush for three or four minutes in a solution of bichloride, 1 to 1,000.

(4) Finally, and this is very important, the hand is introduced moist with the solution, without using any lubricant and without coming in contact with the bed-clothes or anything else more than is absolutely necessary.

After disinfecting the hands in this manner, they are practically sterile, so far as the germs mentioned are concerned, and any extraneous bacteria which should happen to drop on them would very likely be incapacitated for any further harm by the action of the bichloride.

Escherich's bacillus, although a near neighbor in all labor cases, cannot grow nor migrate in the acid secretion of the normal vagina; but if the hand of the attending physician was saturated with feces and then introduced to the os, the bacillus would probably find very good pasturage in the alkaline lake at the upper part of the vagina.

Disinfection of the hands in this manner will not take more than six or seven minutes, and with care during the vaginal examination is ample protection against infection. Of course, the hands must be treated in the same manner for each examination, but then we are told to avoid making more examinations than are absolutely necessary. The last case I attended, I think I washed my hands by the method indicated above some six or eight times in the three hours I was present. Perhaps this was rather excessive. Kelly's method of disinfecting the hands with permanganate and oxalic acid has no advantages over Fürbringer's method, while it has several disadvantages.

NEURALGIA OF THE PENIS.

By ROBERT BOYD, M.D.,

GRAND CAYMAN, BRITISH WEST INDIES.

AFTER careful perusal of authorities upon venereal diseases, such as Keyes, Otis, and others, and not having met before with a similar case in my private practice, I am of the belief that the subject of this article is a new malady and not heretofore mentioned by any writer.

The following is the history of a patient who recently consulted me in regard to his complaint:

C. B.—, male, aged twenty-six years, unmarried; occupation, bookkeeper. For the past two days he has been suffering from severe paroxysmal pain of a lancinating nature, occurring about every half-hour, day and night, and which begins at the root of the penis and extends along the shaft on the right side to the glans penis, when it ceases. As the patient expresses it, the pain seems to run along to the head, and, having no farther to go, it escapes. The duration of the pain is about one minute, and has been so severe as to awake him from sound sleep several times during the night. The patient states that he suffered from the same pains about a year ago, but that they were less severe than at present, and that they gradually disappeared without any treatment. The patient is of sedentary habits, neurotic constitution, and suffers occasionally from severe general headache. There is no history of venereal disease, nor is there any history of traumatism of the penis or perineum. The urethra is in a healthy condition: there is no discharge or tendency to stricture (No. 10 American sound passing easily); micturition is free and non-painful. There is a constant desire to micturate, which desire is exaggerated during the paroxysms of pain. Examination of urine gives negative results.

Bowels are regular. Examination of the prostate gland, per rectum, shows it to be normal.

The patient was directed to sleep on a hard bed, to avoid too much bed-clothing, and erections increased the neuralgia, and the following medication prescribed: Monobromate of camphor, ten grains, and bromide of sodium, twenty grains, every three hours during the day, and one-sixth grain of morphine at bedtime.

The pain gradually subsided, and in four days he was free of it.

I have seen the patient lately, two months since the attack, and so far there has been no return of the trouble.

A CASE OF SEPTIC PERITONITIS—OPERATION (PRIMARY AND SECONDARY)—RECOVERY.

By H. E. KENDALL, M.D.,

ST. JOHNS, N. F.

E. V.—, aged fourteen years, suffering from appendicitis, was seen in consultation on the fourth day of the disease. The symptoms then were those of grave peritonitis. An operation was advised and accepted. The abdomen was opened over the appendix: incision at the right border of the rectus. Sero-pus welled up as soon as the peritoneum was incised. The right flank and pelvis were full of fluid. It extended well up under the liver and among the coils of intestine to the left of the spinal column. There were no adhesions. The cavity was mopped out by the dry method and the appendix was removed. It contained an enterolith, was gangrenous and perforated. The intestines were then well sandwiched between strips of gauze put in every direction, according to the McBurney method, and the incision, about five inches long, was left open. The patient did well and on the sixth day the gauze strips were removed, the sinuses being mopped out and gently repacked. On the eighth day, while gently flushing the sinuses, I observed that the fluid did not return well from that which led to the left side of the pelvis. It had a pretty sharp angle where it passed the pelvic brim, which caused some pressure with rupture of adhesions. That night my patient became very ill, and in the morning when I saw him he had again developed all the signs of septic peritonitis. The percussion note in the left flank, which the day before had been tympanitic, was now flat. I accordingly decided to open on the other side, and did so about eighteen hours after the accident had occurred. The cavity on this side was full of serum. It presented about one-fourth the surface of the general peritoneal cavity, and was limited by the adhesions set up by the former operation. The treatment was the same as in the first case, with the exception that the latter side was flushed with normal salt solution. It is, perhaps, worthy of note that this side so treated discharged serum much more profusely and for a longer time than the first side, treated by the dry method. It would seem, likewise, as though irrigation in the first instance would have caused infection of a portion of the cavity which escaped by the method adopted. The patient had a slow convalescence, about ten weeks. A secondary abscess formed, which after a tedious watching opened through the old wound. Recovery has, however, been perfect. This case seems to me to be of interest on account of the secondary infection and the happy result of the secondary operation. Apart from this, I wish to report it in order to get some light on one or two questions arising therefrom.

(1) I simply ligated and excised the appendix. A small faecal fistula followed, which lasted for four

weeks and closed spontaneously. Should I have adopted the invagination method under the existing conditions of sepsis and gangrene?

(2) I left the gauze drains in until they fairly floated out on pus. I thought it a safe method, and had not the confidence to remove them at an earlier date. Is it necessary for the sinuses to suppurate in these cases? Is there any clear criterion which would permit of the gauze being removed at an earlier stage? Are secondary abscesses more likely to occur if the drains are removed earlier?

MALARIAL HÆMATURIA, OR HEMORRHAGIC FEVER.

By W. D. BUSH, M.D.,

LEESBURGH, FLA.

THIS disease is getting to be a very common occurrence in Florida, Georgia, and the Mississippi bottoms, and as I find very little literature on this subject I think every physician in these regions should make himself thoroughly acquainted with the symptoms and treatment of the affection. Hemorrhagic fever attacks those who have previously had some form of malarial fever, as a general rule those who have their systems full of the malarial poison.

Now, as to the pathology, the chief manifestation is the alteration of the blood and the organs that are disposed to congestion and inflammation, such as lungs, bowels, and kidneys, due to a defibrinated condition of the blood.

The symptoms and treatment I will give by referring to some cases that have come under my observation:

CASE I.—Mr. F—, a man of about forty years, who has been in Florida some eight or ten years; very dark complexion and of a bilious temperament. He had hemorrhagic fever in Georgia and came very near dying. I saw him at 1 P.M. He had a temperature of 104° F., and was perspiring very freely. He was deeply jaundiced over the whole surface; the conjunctivæ were of the same color as the skin. He had passed bloody urine three times and a large quantity at each time. He was somewhat nauseated and the tongue had a yellow coat on it. I gave him at once calomel, gr. vi.; aloin, gr. ss.; podophyllin, gr. ½; sodium bicarbonate, gr. vi. I also left another capsule containing the same, to be taken next morning in case this did not operate well. I also left turpentine, to be given in ten-drop doses every three or four hours till the urine cleared up. I told my patient I would call again before night. So about four or five o'clock I saw my partner, Dr. Green, and told him I had a case of hemorrhagic fever and asked him if he would not like to see it. We drove out and on our way he asked me what I was giving my patient. I told him and also remarked that I intended giving quinine next morning. He said that if I did I would be apt to send my patient to the other world, for he had lost enough to convince him of its uselessness before he stopped the use of quinine and had not lost a patient since. So I decided to profit by some older experience in this disease and not give the quinine. Instead I gave the patient Warburg pills, one every three hours, till five were given in one day, using the two-drachm pills with aloes. I saw him next day. The urine was clear. The mercurial had operated well. There was no fever. The skin was clear and the patient was in a good condition.

CASE II.—Mr. K— had the same symptoms, the same treatment was used, and the patient made a good recovery.

CASE III.—Mrs. B— sent for me on Wednesday.

I was out of town, so she waited, as she thought she had a case of intermittent fever. She grew worse and sent again next day. I found her perspiring and showing all the characteristic symptoms of hemorrhagic fever. She had been passing blood for two days and I found she had been taking quinine all the day before. She was very nervous, nauseated, and vomited black bile. I at once put her on a mercurial, and gave turpentine and Warburg pills. She was very bilious, but by repeated doses of calomel she soon recovered.

CASES IV. and V.—Father and son. Two of the worst cases I ever saw. These, like the rest, had previously had intermittent fever. Their systems were full of malarial poison. These I saw with Dr. Green at 3 P.M. The father had taken the day before thirty to forty grains of quinine. When we saw him the father was perspiring freely; the skin and eyes were most deeply jaundiced. Both patients were vomiting every few minutes black bile and decomposed food. They were so nauseated that it was a hard matter to get anything to stay on the stomach. We at once put them on the mercurial and Warburg-pill treatment. We finally got the medicine to operate. The son was soon convalescent, but to our great surprise as soon as the urine of the father cleared up there was a total suppression. Vomiting was troublesome for some time and there was hiccough. There were then involuntary discharges from the bowels, which were only checked by strong astringents. We tried everything that was ever recommended for suppression of urine, but to no use. We kept off uræmic convulsions by giving pilocarpine, but the patient died from suppression and exhaustion.

INTESTINAL OBSTRUCTION: LATERAL ANASTOMOSIS WITH THE MURPHY BUTTON, INTRODUCED THROUGH THE VAGINA.

By JOHN A. PRINCE, M.D.,

SPRINGFIELD, ILL.

MRS. L—, aged thirty-three years, two children. Vaginal hysterectomy was performed October 2, 1895, for chronic ovarian and tubal disease. Hæmorrhage was obtained by clamps, which were removed on the second day. On the fourth day several free movements of the bowels were obtained. Flatus passed freely from the first day. The patient passed flatus on the seventh day, but all efforts to obtain a movement of the bowels after that date failed. Tympanites was present on the eighth day and rapidly increased. On the ninth day, thinking some obstruction might exist within reach of the hand introduced in the rectum, I gave an anæsthetic, and after dilating the sphincter, passed my hand as high as possible, but could detect no trouble. Her condition, bad before the operation, did not encourage the idea of a cœliotomy. On the tenth day I was out of the city and was surprised on returning to find my patient still alive. I suggested to the mother and husband of the patient, who were present, the bare possibility of being able to reach the point of obstruction by breaking up the adhesions at the vaginal vault and exploring the pelvic and abdominal cavities with the hand. After considerable delay, consent was obtained, and after anæsthetizing and cleaning the vagina the fresh adhesions were broken up. The vault was completely closed by omentum, being firmly united to the edges of the vagina. Whether this is always nature's method of closing the vault or not, I am in ignorance. There was no suppuration present, the wound being as fresh and clean as the day it was made.

I could find no obstruction in the pelvis nor as high as I could reach in the abdominal cavity.

While passing my hand back and forth among the distended intestines a loop of collapsed gut got between my fingers, and I brought it down into the vagina. I made efforts to trace it to the point of obstruction, but they were futile.

The thought entered my mind that a Murphy button might be inserted between this loop of collapsed gut and one of the many distended loops, and an anastomosis made which might save this patient's life. The idea was carried into execution at once, though, owing to the limited area in which I had to work, it was only accomplished with much difficulty. A small rent was made above the button, which was closed as well as possible with sutures. Reaction was slow at first, but when it did set in the woman rallied rapidly. Gas and feces passed freely through the natural orifice until the second day, when some fecal discharge appeared in the vagina. This rapidly increased in amount, and soon, nearly the entire contents of the bowel was discharged through the fistulous opening. As this opening contracted, more and more of the discharge passed through the natural opening, until at this writing, December 2d, there is only an occasional discharge from the vagina. The button passed by the anus November 29th. At the present time the patient is entirely well and able to go about as usual.

This procedure would not be the operation of election in cases of obstruction of the bowels, but in the case reported it was the only thing possible to do, aside from making an artificial anus.

PRIMARY CARCINOMA OF INFERIOR TURBINATED BODY.

By BEAMAN DOUGLASS, M.D.,

ASSISTANT SURGEON, MANHATTAN EYE, EAR, AND THROAT HOSPITAL; INSTRUCTOR, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

THE literature of medicine contains reports of several cases of malignant disease, carcinoma or sarcoma of the nasal passages, but nearly all the reported cases seem deficient either as to the intranasal origin of the growth, or in the diagnosis having been made without the microscope. Data as to the early symptoms of the disease are often wanting also. In looking over the literature of carcinoma of the nose, I find two cases only in which a careful microscopic diagnosis of carcinoma was made and in which the neoplasm clearly began intranasally. In both these cases the disease originated upon the septum. There are no recorded cases in which the lesion began in the turbinated tissues.

The case which is the subject of the following report has a carcinoma beginning with symptoms so few and so slight as hardly to attract serious attention, and yet the history clearly points to the inferior turbinated tissue as the point of origin, and it is only upon this tissue that the disease can be found inside the nose. The consideration of this patient and her history would lead us to believe:

(1) That carcinoma, primary and intranasal, may occur in a form so closely resembling an ordinary rhinitis as to be overlooked, the distinguishing symptoms being pain and the recurrence of nasal hemorrhage.

(2) In all nasal ulcerations of any extent, a careful microscopic examination of a portion of the ulcerated surface is the only accurate means of early diagnosis.

(3) That an early diagnosis affords the only chance of operative interference.

(4) That primary carcinoma of the turbinated is possible and should enter into the differential diagnosis of all nasal ulcerations.

(5) That carcinoma of the inferior turbinated may occur without antrum involvement.

The history obtained as fully as possible from the patient is as follows:

Family History.—The mother is living at the age of seventy-seven years, is in fair health, except for indigestion. The father at twenty-nine years of age was the collector and partner in a grocery business. He developed after a prolonged exposure to cold and wet a discharge from the nose, accompanied by a disagreeable odor. Right-antrum disease developed and the antrum was drained by drilling through a tooth cavity. This antrum disease lasted twenty years, during which time he continued at his business. At the age of forty-nine the right eye became inflamed and an abscess developed over the frontal sinus on that side. This was lanced and a large quantity of pus was removed. The affection of the antrum during this time remained stationary. He then lost flesh and strength rapidly, became bedridden, and after seven months the physician in charge called in consultation Dr. Hodgins, of St. Louis. The frontal sinus was opened, some necrosed bone from the centre of the forehead was removed, and the patient died ten days afterward. There is no history of syphilis, and, except that the patient's two sisters had some slight eye trouble, there is no record of further hereditary taint in the family.

My patient, Mrs. H—, aged thirty-one and a half years, presented herself for examination at the office of Prof. O. B. Douglas, and it is through his kindness that I am able to report the present case. The patient has always been delicate and nervous, and yet well if we except the usual category of children's ailments, all of which she proudly asserts she has had. The nose first troubled her about five years ago, when she complained of a mucous discharge from the left side. The discharge has been at times rather scanty, forming scabs, which when removed were always followed by slight bleeding. One year ago the patient suffered from a severe nasal hemorrhage and this has since been repeated at irregular intervals. There has been pain in the nose only during the last three months. The pain has been neuralgic in character and confined to the left side of the face. She has never suffered headache. One year ago patient noticed the first external deformity. The left side of the nose became slightly swollen and the left nasal orifice was slightly lifted upward. There was no discoloration of the skin. The nose remained in this condition until three months ago, when upon the left nasal bone and the left nasal process of the superior maxillary two small bony lumps appeared, which have gradually merged into one. About this time the skin became discolored and the superficial blood-vessels of the skin became dilated. The left lachrymal duct has been obstructed somewhat for about a year, but the obstruction seemed to vary; at one time the tears would flow freely over the cheek, at other times for several weeks hardly at all. The patient has not failed in flesh much, but is very weak and easily prostrated. She has had one child.

Present Condition — Examination. — The right naris is normal; the pharynx and post-pharynx appear normal; the right side of face presents no deformity. The left ostium narium is slightly retracted upward about one-eighth inch and the ala with it. The intranasal mucous membrane, except for that covering the inferior turbinated bone, presents no change macroscopically. The inferior turbinate is quite innocent in appearance and would perhaps be easily overlooked except for the history of bleeding without any other catarrhal symptoms and the extreme prostration of the patient, together with the external deformity. This left inferior turbinate seems atrophied or at least occupies less space than its opposite. It extends below

nearly to the floor of the nose, but does not lie in contact with it. The surface is superficially ulcerated, is not covered with pus or blood. It bleeds easily when touched. The ulcerated edges are without thickening or induration. The surface of the ulcer is not excavated, but is flush with the surface of the surrounding mucous membrane. This surface has a roughened appearance and looks not unlike an atrophic ulceration from which the scab has been newly removed.

The ulceration begins in front, about one-fourth inch from the anterior end of the inferior turbinate, covers the whole of the turbinate on top, inside, and below, and extends back about one inch; the posterior end is not ulcerated or enlarged. Two pieces of tissue were removed from this ulcer, one corresponding to the lower border of the inferior turbinate and the other from the inner surface. The pathological report, signed by Henry T. Brooks, M.D., pathologist, Post-Graduate Medical School and Hospital, is as follows: "The piece of tissue from mucous membrane of the nose sent me for examination shows all the characteristics of a carcinoma."

The external deformity consists of a hard nodule on the nasal process of the left superior maxillary, about three-fourths of an inch in diameter, not adherent to the skin, but the cutaneous blood-vessels are dilated. There is obstruction of lachrymal duct and tears flow over the cheek. The whole of the left nasal region seems somewhat deformed and the left ala is retracted upward and outward. The conjunctiva is congested at times. There is no exophthalmos and no displacement of orbit.

A few days after the case came under my observation the cellular tissue of the eyelid suddenly swelled till the œdema closed the eye; in the inner corner of the upper eyelid a small nodule appeared and has persisted, tender and swollen, since the subsidence of the œdema.

The case was transilluminated with negative results. Both antra transmitted the light equally. Over the external bony deformity the light was somewhat obstructed, less clear but remaining translucent.

(From case book, May 3, 1896.) "Patient to-day has left nasal cavity filled with a white crust; this is cleaned away with peroxide of hydrogen and an oily spray, showing the meatus clear. The light shines through to the posterior pharynx. There is no discharge, no tumor. The appearance of ulcer on the inferior turbinate same as before. The posterior end of turbinates normal in appearance. The external bony nodule is quite prominent, about three-fourths of an inch in diameter. The swelling at inner canthus on upper lid has nearly subsided. The treatment is cleansing, tonic, and expectant."

Hydrogen Dioxide and Saline Solution.—Dr. Robert T. Morris (*American Medical and Surgical Bulletin*, May 9, 1896) says: "If we fail to destroy pus and septic fluids when opening an appendix abscess, the general peritoneal cavity is likely to become infected. Hydrogen dioxide and physiological saline solution are the sheet anchors of clean appendicitis work, and I would lose a few cases from post-operative septic peritonitis if either one of these resources was omitted. I do not know what surgeons mean when they speak of leaving the free peritoneal cavity unopened, as a rule, in appendicitis abscess work. There are few cases in my practice in which it is not necessary to expose uninfected peritoneum at one or more points. But what is the harm if abscess cavities are properly cleansed with hydrogen dioxide and saline solution? I have so much confidence in our resources to-day, and in the ability of the peritoneum to manage infective processes, that fear of infecting the peritoneum does not enter into my calculations."

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE DROUGHT—DANGER OF WATER FAMINE—NEW "NOMENCLATURE OF DISEASES"—BATTLE OF THE CLUBS—MEDICAL-AID COMPANIES—QUACKERY AT GLOUCESTER—GENERAL MEDICAL COUNCIL—COLLEGE OF SURGEONS P. AND V.P.'S.—MEDICAL DEFENCE AND PROTECTION—OPIUM EATING AND SMOKING—AN INDIAN "CRITIQUE ON THE ROYAL COMMISSION"—A KEATS BED AT A HOSPITAL—BURNS CELEBRATION—EDINBURGH DEATH RATE—ROYAL INFIRMARY HOSPITAL SUNDAY FUND—REPORTS OF DR. THORNE AND THE ADULTERATION COMMITTEE—DR. BEALE, F.R.S.

LONDON, July 17, 1896.

A LONG course of fine hot weather has brought about some alarm as to the water supply. The drought has been so pronounced that the grass in the parks has been lighted by the careless throwing of matches among it, thus producing a miniature prairie fire. A number of deaths attributed to the heat have also been recorded in various parts of the country. Mr. Symons, F.R.S., director of the Rainfall Association, feels no alarm at the dryness of the last four or five months, and expresses a belief that there is plenty of time for 1896 to take a place among wet years. Few people are equally sanguine, and in some parts a water famine seems approaching. The East London Water Company has already found it necessary, as a precautionary measure, to cut off the supply from nine o'clock at night till six in the morning, and it is stated that in one part of its district there has been no water distributed for the major part of a week. One of the western companies is also considering the necessity of curtailing their supply, the other companies apparently being satisfied that they will be able to meet the demands upon them. Perhaps these fears of water famine are premature, for in various parts of the country heavy thunder-storms with enormous downfall have already succeeded the great heat, caused by the high barometrical pressure which has now passed by. In London the fall of temperature was equally sudden and welcome.

A third edition of the "Nomenclature of Diseases" has been published, but only a few have received their copies. The treasury has sanctioned a gratuitous issue to every member of the profession, so that in a short time this edition will supplant its predecessor. It has been very carefully revised by the committee of the Royal College of Physicians, appointed four years ago, twenty-four separate sub-committees having occupied themselves with the several sections. The names of diseases are given in English, Latin, French, and German. The column of Italian names has this time been omitted, as they do not materially differ from Latin or French. The list of names follows as closely as possible the terms employed in the office of the registrar-general, so as to avoid the confusion which would necessarily occur if the past statistics of that office were rendered difficult or impossible of comparison with future figures. Accuracy of nomenclature, facility of comparison, and continuity of records are more important in a work of this kind than pathological classification. The English index has been separated from the Latin, the latter being intended rather as a guide to those who do not know English than for other purposes. Nevertheless, it is very full and accurate. It was commenced by the late Dr. Greenhill and has been completed by Dr. Perry. The work, altogether, is certainly equal to its predecessor.

For several months past "the Battle of the Clubs" has been a stereotyped heading in our journals. Under it a series of fights have been recorded, so that "the campaign" or "the war" would be more expressive of the contest which has been going on in many parts of the country between the managers of friendly societies and medical men. The war, which broke out in Cork, and of which I gave you an account at the time, has extended to many towns in England, and unless the clubs listen to reason may become universal: for it is undoubted that the system is everywhere abused. Originally intended to meet the necessities of the poorer members of the working classes, the doctors' fees of these clubs were fixed on a charitable basis. Nevertheless, not only skilled workmen and foremen availed themselves of these terms, but tradesmen, publicans, town councillors, and other well-to-do people joined the clubs as honorary members. Many were too proud to draw the usual sick allowance and so proclaim their meanness to every member of their club, and at once raise the question as to whether it would be right to do so. But the doctor's fee of £2 6s. or £3 6s. per annum having been subscribed, these same persons made their demands on the doctor's time without scruple. This is the fact put forward as the chief reason of the medical revolt; at the same time it must be remembered that in all cases the fees are too small to be remunerative, and, free as all doctors have always been with their charitable help, they cannot but feel aggrieved with those who have larger incomes than their own, but seek to impose on them for assistance.

Other grievances are the increase of cheap dispensaries, the abuse of the out-patient departments at hospitals, and the recent developments of the joint-stock principle in the shape of medical-aid associations. These last engage a medical man to attend all their members in a district, paying him a small salary, and by dint of touting get large numbers to enter as members, thus loading the unfortunate doctor with continual work for the barest pittance and making a profit out of his labors, in which he does not participate. This practice is condemned in all professional circles, and the "sweating" of doctors for the benefit of others must, it is held, be put an end to. The matter has even been brought before the Medical Council, but nothing has been done, though it is expected that outside pressure may eventually lead to some effectual resolution. Many years ago I was paying a long visit in a manufacturing town, where a very large proportion of the population belonged to clubs, and a difficulty had arisen which was met in the following manner: Each of the doctors—there were five in the town—opened a club of his own; that is to say, he entered in a book the names of all patients who had been in any of the clubs of which he had been doctor and who were willing to pay a weekly or monthly sum. In return for this the doctor engaged to attend them as he had previously done under the club system. A collector was engaged to call for subscriptions, and as long as they were paid regularly medical attendance was insured. There were no other rules, and the members were to all intents and purposes on the same footing as private patients, and could, of course, change their doctor whenever they pleased. As each of the doctors attended on the same conditions there was no competition as to prices, and every man could choose his own doctor. This plan gave satisfaction and might now be tried, perhaps, in other places. Something of the kind has, I hear, been done in Coventry, where a kind of medical service has been established in self-defence. As soon as the work of a medical aid association was thrown up, a qualified man was sent into the town to carry it on; and this illustrates the chief difficulty of fighting these trading societies. In some towns the fear of a new man being introduced has

sufficed to prevent union: but even at Coventry I am told the plan has been fairly successful and promises still better results. This shows that it is only necessary for the medical men to act together to defeat the scheme of limited companies absorbing the profits of their labors.

An almost incredible instance of gross quackery is reported from Gloucester, where it appears that during the epidemic an unqualified man, calling himself a hydropathist, started in the town with large professions of curing small-pox and preventing its spread. Patients, as usual, did not fail him, and I hear that not less than twenty-three of his cases were fatal. Where is the coroner? No inquests seem to have been held, and on what authority the deaths have been registered might well be inquired into. The inaction of the coroner lays upon him a grave responsibility.

As I anticipated, the coming election to the General Medical Council has been seized upon by the British Medical Association or some of its leaders in the hope of once more putting in their nominees. Drs. Woodcock and Drage are excellent candidates and could well have afforded to stand alone, but have naturally accepted the advances of the association, which I am sorry to see has again "nobbled" Dr. Glover, whose position, after ten years' work on the council, ought to be so secure as to prevent his accepting extrinsic aid and so far tending to restrict the choice of the electors. Yesterday there was a meeting at the rooms of the Royal Medical and Chirurgical Society, to hear addresses from these three gentlemen. As I have reported, other candidates have declared themselves, but with the wire pulling of the association against them they have scarcely a fair chance. I should like to vote for Dr. Glover, but this union with a great association is so interfering with the freedom of electors that I hesitate, and I know that many others feel the same, and some are really indignant.

At the meeting of the new council of the Royal College of Surgeons, Sir William MacCormack was elected president, and Messrs. Macnamara and Langton vice-presidents, for the ensuing collegiate year.

LONDON, July 24, 1896

THE proposed amalgamation of the Medical Defence Union with the London and Counties Medical Protection Society seems finally to have failed, as the two cannot agree on the name to be registered, each pretending that its own name is valuable as "good will." Some of us would say: "What's in a name?" To register the combination as the "Medical Defence Union, with which is amalgamated the London and Counties Medical Protection Society," and so render that long description the only legal name, certainly seems preposterous and would lead to curious remarks in court. If both names must be expressed, why not reduce it to London and Counties Medical Union? But the question of defence will be further discussed, as the British Medical Association proposes to take it up. For this purpose its memorandum must be altered, and that is rather a serious step, for the necessary legal proceedings are very complex. A special meeting has been held at which it was resolved to initiate the change. Only a handful of members was present, but great differences of opinion were expressed. Another special meeting has been convened, to be held at the Carlisle assembly, when the matter may be fully discussed. There are four or five schemes for carrying out the intention, and a certain degree of interest is exhibited in them. If the association, with its large numbers and great income, can agree upon a practicable scheme and get legal authority and commit the management to an able board, much may be done, and the members would be insured against vex-

ations actions. The two protection societies might, perhaps, be absorbed, and the men who have worked them so well should find places in the executive and be trusted to carry out on a larger scale work for which they have evinced so much talent.

You will remember that the opium commission reported somewhat unexpectedly in favor of rather than against maintaining the present regulations respecting the traffic in India. It was inevitable that this report should excite keen criticism, and the *Indian Medical Record* devoted a series of articles to combating the memorandum of Sir William Roberts, the medical member of the royal commission. These articles have been revised and are now being circulated in pamphlet form. Sir William Roberts' views are subjected by the *Record* to severe criticism, founded on careful examination of the facts. At the outset it is remarked that the qualifications necessary for a medical expert are wanting in Sir William Roberts, that he has fixed opinions on one side, and that the India office was wise in selecting one who was almost certain to express official views. Sir William Roberts attributes a dual character to the opium habit—the medicinal and what he calls the "euphoric." This last term, he says, "means feeling perfectly well and able to bear pain and anxiety easily; but only a select portion of the population are susceptible to the euphoric effects." He takes it for granted that the habit prevails in excess in malarious districts, but this notion is completely exploded by the critique before me, which shows that in Bengal the minimum of consumption is in the most malarious districts, while excess prevails where there is little or no malaria. The real origin of excess seems to correspond with the cultivation of the drug, for wherever it is grown it is eaten, and the more grown the more is eaten. In some districts where it is not grown, but where the habit prevails, the explanation is found in the fact of past cultivation. Further, the distribution and prevalence of the habit has no relation to the medicinal qualities of the drug; but as to its so-called "euphoric" effects it appears that Indian physicians would laugh the idea to scorn. There are many startling statements in the report of the commission, but none, perhaps, more surprising than that the ryots of eastern Bengal use opium as a household remedy, although this statement has been supported by Dr. Crombie. It is, however, shown in the pamphlet mentioned that this is not and cannot be true.

As to the question of a prophylactic influence, Sir William Roberts has revived the exploded notion which attributes antiperiodic properties to anarcotine; but I do not suppose any therapist will be ready to support him, for an efficient dose of this constituent would be accompanied in opium with a dangerous amount of morphine. Our critic apologizes to Bengal physicians "for being obliged to drive the phantom of opium as a prophylactic into the congenial atmosphere of fiction, whence it first emerged." It is startling to find that Sir William Roberts would not interfere with the practice of giving opium to children—a custom for which great responsibility rests on the government of India and which has been so often denounced as cruel and criminal. Another point in reference to this question is the relation of suicide to the opium habit; and here, again, the memorandum of the official expert is shown by his critic to be altogether erroneous. Again, the relation of the habit to food is treated in the report in a very one-sided manner, which the writer of the critique effectually exposes. The views of Drs. Crombie and Cobb, as they appear in the evidence, contradict and so destroy each other, and afford the critic no little merriment.

Smoking opium is a modern habit compared with eating it, and no one has ventured to come forward

in defence of the smoking-dens. The anti-opium agitation really derives its force from the evils of the smoking-habit, which is so rapidly spreading, owing to the regulations of the government on account of its contribution to the Indian exchequer. It is a "social and public vice," says our critic; "hence, more calculated to propagate than the unostentatious and less pernicious habit of opium-eating." When the royal commission was appointed, the smoking-habit in China and the far East was supposed to be the chief subject of inquiry; but it seems that official influence has managed to make this quite secondary and to give the opium-eating habit the most attention. There is a general consensus of opinion that opium-smoking should be abolished, and it is admitted that smokers themselves think so. Even the commissioners admit that "native public opinion condemns the habit as disreputable, and this opinion is shared by the great majority of European witnesses—official and private—including medical practitioners." Nevertheless, Sir William Roberts seems to constitute himself an apologist for this habit.

A blue book on the consumption of opium in India in 1892 reported that the government decided that the total prohibition of smoking-shops was the right policy to follow. The local governments of Bombay and Bengal have, however, managed to prevent this being carried out. New regulations, indeed, were issued, but have failed, and the pamphlet shows that the habit has continued to spread and is likely to do so until the imperial government alters its methods. As an appendix to the pamphlet, the evidence of Dr. Mookerjee, the first native practitioner ever elected to the presidency of the Calcutta Medical Society, is given, and he is supported by the vast majority of Indian physicians. He urges that the vice of opium-smoking should be restricted by legislation, that the preparations used for smoking should not be allowed to be manufactured, and he hopes that the commission on the subject will be followed by one on alcohol, and that England will be induced to deliver India from drunkenness and opium-smoking.

It is proposed to endow a Keats bed at Guy's Hospital, in memory of the great poet who left medicine for the muses. One thousand pounds is wanted for the purpose.

We have just had a Burns celebration, and though we cannot claim him as belonging to the profession, his hatred of shams was expressed in his "Death and Doctor Hornbook," which is one of the most scathing satires on quackery ever penned.

Edinburgh has been rejoicing in a low death rate for several months. For many weeks rates of thirteen and fourteen per thousand have been recorded. For the last three weeks, thirteen, fourteen, and fourteen were the numbers registered.

The Edinburgh Infirmary is to have a new medical pavilion. The architect's plans have been accepted. The estimated cost is £30,300. Plans have also been approved for a new laundry for the infirmary, although Sir Henry Littlejohn pointed out that it was very undesirable to have this laundry in so close proximity to the hospital as on the site selected.

The Hospital Sunday Fund has now reached the sum of £43,200, and some additional donations are expected. Sir S. Crossley has promised a further £1,000.

Dr. Thorne Thorne's third annual report as medical officer to the local government board has just been issued. It is exceptionally instructive and valuable.

The report of the select committee on the sale of foods and drugs has also been issued. It proposes some drastic legislation against adulteration, which if enacted would be a great protection to the public.

Dr. Lionel S. Beale has resigned his professorship at King's College and his physiciancy to the hospital. He held the physiciancy forty years and was a professor rather longer.

"HERMAPHRODISM (?)."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Seeing in the MEDICAL RECORD of July 25th, just received, a report of "A Case of Hermaphrodisism (?)" by Dr. Carl Beck, with four illustrations, the first two of which represent the usual form of spurious hermaphrodisism, viz., imperfect development of the male genital organs, I proceeded to read the article with curiosity to discover wherein this case differed from the numerous instances of this malformation which have come under my observation. I read on without perceiving anything peculiar until I came to the description of the "infundibulum" beneath the arch of the pubes and the discovery of "a canal four inches in length (undoubtedly the vagina) at the end of which a well-developed uterus could be felt."

On reading the above statement, which I quote in the words of the author, I thought that at last a living subject had been found with unquestionably male external sexual organs and with a vagina and uterus (and probably ovaries) representing the internal female sexual organs.

What was my surprise, however, to find absolutely no mention made of the condition of the internal sexual organs when the abdomen was opened for the removal of the mysterious abdominal tumor, which, as might have been expected, proved to be the right testicle and (although the author does not distinctly say so) probably the left testicle also. I naturally expected to see the upper portion of the "well-developed uterus" which had been felt through the canal, four inches in length, "undoubtedly the vagina," mentioned, and perhaps (*mirabile dictu!*) the uterine appendages. But the author appears to have entirely overlooked the glorious opportunity offered him (which I regret to say has never been tendered me) of verifying through an abdominal incision the presumptive diagnosis of true hermaphrodisism. The case as he reports it is simply one of the very common congenital malformations of the external male generative organs (of which I have seen several dozen at least), with small but erectile hypospadiac penis, blind perineal pouch (sometimes three to four inches in depth), thick bilateral scrotal folds, simulating labia majora, and testicles either in the scrotal folds or in the inguinal canal, besides fairly distinctive general male habit.

The only interesting feature in the case seems to me to be the sarcomatous degeneration of the intra-abdominal testicles. The title of "Hermaphrodisism (?)" therefore is not justified even with the interrogation mark, for the case was simply one of hypospadiac male with undescended sarcomatous testicles.

I think the author owes us an explanation of his diagnosis of the "well-developed uterus" which he felt through the "canal" ("undoubtedly the vagina"), and I shall look with interest for the reasons which induced so careful an observer and expert an operator to omit the demonstration of the very point which would have made his case remarkable, if not unique.

PAUL F. MUNDÉ.

NEW YORK, July 27, 1896.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Referring to Dr. Beck's article in the MEDICAL RECORD of July 25th, it seems to me a pity that the report should be so vague, especially on a subject concerning which sufficiently attested cases are much needed.

Judging from the report, the patient seems to have been a female with an enlarged clitoris. His (?) voice, face, form, mammae, and, if I may judge from the photograph, arrangement of the pubic hair were feminine. Was the pubic hair continued up to the umbilicus, as in the male, or did it stop short at the mons veneris, as in the female? The groove on the ventral surface of the penis (?) may have been simply a continuation of the female vestibule, and the cutaneous prominences remains of a female frænum. The urethra and introitus vaginae, hymen, vagina, and uterus were female in character, the two lateral openings probably openings of Bartholin's glands (could their secretion be examined?). These glands empty themselves during sexual excitement in women, and an enlarged clitoris might admit of coitus after the fashion of the male.

Was it the tumor which Dr. Beck removed which he describes as having been recognized as the right testicle, and why was it so recognized? Fig. 3 looks like an ovary, not a testicle, and no report is given of its structure; and if Fig. 4 be the so-called testicle, was testicular tissue recognized microscopically?

Altogether, as a reader, I would point out that Dr. Beck's case as reported is utterly valueless to the collector of statistics, when surely careful microscopic search for ovarian or testicular rudiments might have made it of the utmost consequence to teratologists. Fuller examination of the specimens might make the case one of great value.

WILLIAM KEILLER, F.R.C.S. Ed.,

Professor of Anatomy, University of Texas.

THE APPENDICITIS CONTROVERSY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Years ago I was called in consultation to see a bright young physician who had appendicitis. He had a high fever, up to 103° F., and severe pains for forty-eight hours, but the symptoms were subsiding when I saw him; the next day his temperature was only 99° F., and nearly all the symptoms had disappeared. I told him there was no question about his getting over this attack; that an operation could be talked about later. I was obliged to leave the city, and twenty-four hours after he had a sudden change for the worse, with high fever, chill, and severe pain, and when I returned twelve hours later he was *in articulo mortis* and an operation was of no benefit. With every case of appendicitis, there arises before my mind the picture of that bright young doctor and his poor, six-months-pregnant wife.

Every case of appendicitis must be operated upon immediately; to-morrow it may be too late. I seldom, if ever, meet with a refusal; the patients always say yes. After years of experience, I never varied from this rule until two months ago, when I had a case in which the symptoms had all subsided, and I thought the patient would recover without operation. I waited until the next morning. I found that the pulse had increased in frequency, although the temperature was only 99° F. I operated and found a gangrenous appendix surrounded by pus. Fortunately the patient recovered, but by deviating from my rule and hesitating a life was nearly lost.

I have had general practitioners tell me that they see a good many cases of appendicitis and the patients all get well without an operation; but those very same physicians have cases within the next six months in which the patients die. I know a number of such cases in which two or three patients have died in the hands of these men. That has cured them; they now advocate early operation. Having seen a few cases which recovered, they thought they all recover. We,

who operate a great deal and see the terrible results of waiting, naturally become radical. We insist that the only safe way is to operate in every case promptly. We admit that in ten or fifteen per cent. of our cases the patient would recover without an operation and without recurrence, but in the present state of our knowledge we cannot pick out the one from the other. We must, as the boys say, go it blind. But we do know that in a hundred consecutive cases operated on promptly our mortality would be very low, while out of a hundred consecutive cases treated without operation the mortality would be large; and those who would recover would be subject to two, three, and many more attacks, and with every recurrent attack ten or fifteen per cent. would die. They would not only be in constant danger, but would have the constant worry and the dread of recurring attacks; no peace day or night, summer or winter; at home or travelling about, the sword of Damocles will always hang over them; while, if we operate on them and cure them, the mind will be at peace and they can enjoy life.

Dr. MacArtney, who started this controversy, takes a somewhat different stand. He simply claims that cases occurring in the country, away from skilled operators, should rather be trusted to the *vis medicatrix nature*. To this we all agree. Such cases need but seldom occur. It is wonderful how easily the patient can be removed one hundred or two hundred miles on a stretcher, taken from the train to an ambulance, transferred to a well-equipped hospital, and operated on by an experienced man. And if the patient cannot be moved on short notice, an experienced man can be got in almost any part of the country within a very few hours.

I admit the force of the argument of the fee, which seems to be the *bête noir* of some general practitioners, yet I have known experienced men to travel fifty or one hundred miles and operate, in order to help some fellow practitioner, for a merely nominal sum, when the patient could not be brought to a hospital. Many hundred such cases are operated upon gratuitously. Surgeons sometimes get large fees, but these are few and far between. Some general practitioners claim that if they give up the patient the specialist gets the fees. Those simply betray selfishness.

I would conclude, then, by saying that since appendicitis is a treacherous disease, changing from an apparently mild case to a most virulent one within a few hours, the only safe treatment is prompt operation. It does absolutely no harm, nor does it increase the danger when performed by an experienced surgeon with aseptic surroundings. Secondly, when such cases cannot be moved to a hospital, an experienced surgeon can be obtained, within a very short time, in any part of the country. The question of fee does not enter into the controversy at all and is unworthy of being mentioned by an honorable practitioner.

New Instruments.

SOME NEW INSTRUMENTS FOR THE TREATMENT OF RECTAL DISEASES.

By SAMUEL T. EARLE, M.D.,

PROFESSOR OF DISEASES OF THE RECTUM AT THE BALTIMORE MEDICAL COLLEGE.

IN the treatment of internal incomplete fistulæ with their openings just between or over the sphincter muscles, also abscess pockets formed between the columns of Morgagni, I have heretofore found great difficulty in getting the ordinary curved bistoury into these openings, and it suggested itself to me that a bistoury with

FIG. 1.

the complete curve, or, what might be better understood, a hawk-bill bistoury, would meet the difficulty successfully. I accordingly had one made, the cut of which is here submitted (Fig. 1). I have found it to answer the purpose admirably, and would recommend it to those working in this line.

Since the time that I began to devote special attention to rectal work, more than eleven years ago, I have found the rectal specula that I have tried (and they have been many and of various patterns) most unsatisfactory, either in not fulfilling the object for which they were designed or in being painful to introduce. Some four years ago, when in search of a satisfactory rectal retractor, which I have yet been unable to find, a gynecological friend suggested and gave to me for trial a Neugebauer's vaginal speculum; while I found it entirely unsuitable for the purpose of a retractor, it proved itself by far the most efficient and satisfactory rectal speculum that I have ever seen. It is here necessary to explain that only one blade of this instrument is used for this purpose, its use in vaginal work requiring the double blade. I found the curve and the point exactly adapted to the conformation of the parts, so that it can be introduced with less pain to the patient than any rectal speculum I have ever seen. The principle on which it acts is exactly similar to Sims' vaginal speculum.

With the hips slightly elevated in Sims' position, the instrument merely dilates the sphincter with the greatest possible ease; the air, rushing in, distends the rectal wall, giving an unobstructed view. The original instrument did not have a satisfactory handle for rectal work; so, after proving its practicability for four years, I then designed my present speculum, retaining entirely the original model of Neugebauer's speculum, as herein given (see Fig. 2), which represents the instrument closed, one-third size, merely adding a convenient handle, which is attached to the blade by a hinge, permitting it to be folded into a small space. There are two sizes, one for children and one for adults.

FIG. 2.

I would heartily recommend the trial of this instrument to physicians, feeling confident that it will prove entirely satisfactory.

A NEAT SPHERICAL GAUZE SPONGE.

By G. W. PERKINS, M.D.,

OGDEN, UTAH.

SINCE the general use of heat for sterilization, gauze has largely replaced marine sponges in surgical work. Flat pads made up of several layers of gauze, and spherical sponges made by enclosing masses of loose gauze or absorbent cotton in an envelope of gauze, are the forms in which it is usually employed.

The flat pads are easily folded in such a way as to place all raw edges of the fabric in the inside of the pad, and a few long stitches serve to keep them there. The spherical sponges which I have seen described and figured have been made by simply tying the enveloping layer of gauze and cutting off the excess a short distance beyond the ligature, thus leaving this cut surface with threads of the gauze projecting. This seems to me undesirable, because some portions of these threads might become detached and be left in the wound or cavity in which the sponge had been used.

In casting about for a way to obviate this disadvantage, I first made the sponge as above described, but went one step farther by carrying around the projecting stump a circular purse-string suture, and in tying this pushed the stump into the centre of the sponge, thus burying it out of sight. This answered very well, but left a hard lump at one side of the sponge, which sometimes interfered with grasping it in a sponge-holder. I next tried the following manœuvre, by which I succeeded in making as neat and satisfactory a sponge as one could wish for. Instead of ligating the pedicle of the envelope of gauze, I twisted it once or twice and grasped it with a small hæmostatic clamp; then cut away the excess close to the outer side of the clamp and placed my purse-string circular suture about half an inch distant from the stump, and as I tied it pushed the clamp holding the stump of the pedicle into the sponge, disengaging and withdrawing the clamp just before the suture was drawn tight.

The result is a symmetrical, sub-spherical mass of loose gauze, without raw edges on its surface and without hard lumps in its substance, which has in my hands admirably answered its purpose.

This is merely an adaptation of the Dawbarn method of inverting the unligated stump of the appendix into the cæcum, and I dare say has been used before by other surgeons; but as I have never seen it in print, I offer the suggestion for what it is worth.

The Spermatic Fluid in Secondary Syphilis.—

According to Dr. Rochon there may exist in the secondary period of syphilis, either in the seminiferous tubes or in the spermatic cord, manifestations capable of contaminating the semen and making it infective. These manifestations are aided by inflammations of any kind, and in particular by gonorrhœa, the pus of which thus becomes doubly dangerous. All acute or chronic non-syphilitic affections of the prostate and ureter may, in the secondary stage, mingle virulent blood with the semen, and thus render it inoculable. This added virulence of the semen may manifest itself by chancres of the integuments accessible to examination, and also by intra-cervical or intra-uterine chancres, especially if the intercourse at which infection takes place is followed by conception. There is thus no longer a relation of cause and effect between conception and syphilis; but there remains, nevertheless, a close link of necessary coincidence, owing to the modifications of the uterine mucosa at the time favorable to fecundation. This link is close enough to justify the retention of the term syphilis by conception.—*La Médecine Moderne.*

Pathological Society of Philadelphia.—At the stated meeting of the Pathological Society of Philadelphia, held on May 28th, in conjunction with the Philadelphia Neurological Society, an exceedingly interesting and instructive programme was carried out. An initial report of the work of the neurological laboratory of the Philadelphia Polyclinic was presented. In a communication entitled "Lesions of the Nervous System in Acute Yellow Atrophy of the Liver," by Drs. C. W. Burr and A. O. J. Kelly, degenerative changes were described in the cells of the cerebral cortex comparable with those observed in other intoxication processes, experimental and pathological. Dr. A. O. J. Kelly presented sections of the cord from a case of paraplegia in an old man, showing thickening of the blood-vessels and increase of the neuroglia of the cord; and also sections of a cord presenting the classic changes secondary to fracture of the vertebræ. Dr. J. H. W. Rhein related a case of ataxic paraplegia and presented sections of the cord, showing the usual sclerosis of the posterior and lateral columns of the cord. Dr. H. D. Boyer reported a case of Pott's disease and demonstrated sections showing myelitis with ascending and descending degeneration. Dr. Mary A. Schively described with much detail the histological changes found in a case of syphilis of the brain and presented many illustrative photographs and sketches. Drs. F. White and W. G. Spiller showed brains from two cases of infantile cerebral paralysis. One was from a hemiplegic child, the other from a diplegic. The former presented the lesions of vascular occlusion, the latter the condition of defective development (microcephalus), with secondary changes in the cord. Dr. Spiller also exhibited a specimen treated with Weigert's new neuroglia stain, showing only the cells and the fibres of the supporting structure of the cord. Dr. H. M. Fisher reported a case of caries of the lumbar vertebræ with myelitis and ascending degeneration, and presented histologic sections. By invitation Dr. Woods Hutchinson, professor of comparative pathology in the University of Buffalo, made some remarks on that subject. Dr. B. F. Stahl reported a fatal case of diphtheria of the uterus. Dr. D. Riesman presented specimens of Charcot-Leyden crystals from a case of bronchitis, and spoke of the theories offered in explanation of their origin and discussed their relationship to other similar crystals found in the body. A resolution was unanimously adopted protesting against the passage by Congress of a bill restricting vivisection in the District of Columbia.

Wanted, Another Doctor.—"If I was pa an' ma," said Willie, "I'd hire another doctor. The baby we got last time wasn't finished. It hadn't a tooth or a hair."

THE DISORDERS OF THE MUSCULAR SYSTEM IN INSANITY.¹

By THEODORE H. KELLOGG, M.D.,

NEW YORK CITY,

LATE MEDICAL SUPERINTENDENT OF WILLARD STATE HOSPITAL, NEW YORK.

INSANITY, viewed in its broadest clinical relations, may be defined as a reflex psycho-somatic manifestation of a diseased nervous system.

In the vast majority of cases it will be found that the presidial functions of the entire nervous system, as regards internal organs, the muscular system, circulation, respiration, digestion, and secondary metabolism, are all involved in the symptom complex of insanity.

One of the practical means of advance in psychiatry therefore lies in the faithful study of the bodily phenomena of insanity. In pursuance of this idea, and as the continuation of a series of articles already published on the somatic symptoms of mental disease, viz., on "Disorders of Speech," "Modifications of Respiration," "Pneumogastric Disorders," and on "The Pulse in Insanity," this present paper on "The Disorders of the Muscular System in Insanity" is now presented for the consideration of my hearers.

Attention will be directed first to the striped muscles, constituting the voluntary muscular system, which serves all purposes of adaptation to external relations, and then to the unstriated muscles, those of organic life, as found in the viscera and vascular supplies of the organism.

In the first place, then, it is well to recall for one moment the main anatomical and physiological points in the nervous mechanism which presides over the innervation of the voluntary muscular system. The prime source of motor innervation for the voluntary muscles is the cortex of the brain. The motor impulses originating in cortical areas are conveyed downward by the nervous fibres which converge to form the pyramidal tracts and by the latter to the motor cells of the anterior cornua of the spinal cord, and from thence by the anterior roots to the motor nerves and to their peripheral distribution in the voluntary muscles. Thus, the local pathology of the disorders of the voluntary muscular system may be, as will appear more fully later on, disease of the brain cortex, as in the degeneration of cortical areas in general paresis; solution of continuity of the fibres which go to form the pyramidal tracts, as in internal capsular lesions in organic dementia; morbid changes in motor cells of the anterior cornua of the spinal cord, as in the sclerotic processes of alcoholic dementia; or disease of the peripheral nerves, as in the multiple neuritis of toxic insanity.

The above are the main points of localization in the morbid anatomy of the muscular disorders to be mentioned. Some of these disorders, however, are of unknown pathology throughout their entire course,

¹ Read before the American Medico-Psychological Association, at Boston, May 28, 1896.

and still others, like the paralysis of hysterical insanity, though functional at first, through prolonged vasomotor and trophic changes finally pass into the category of affections having distinct organic lesions.

The description of these muscular disorders will now proceed somewhat in the order of the frequency with which they are encountered in actual clinical practice, and the first one to receive attention is atrophy.

Atrophy of voluntary muscles is much more frequent in insanity than is supposed, and careful measurements and tests as to muscular dimensions should form a part of the daily clinical study of insane patients. The general loss of bodily weight, which is almost universal in all acute stages of insanity, is largely due to general atrophic changes in the voluntary muscular system. Even in the chronic stages of mental disease the malnutrition of striated muscles may proceed so far as to amount to a tropho-neurosis, which is only a part of the more general neurosis of which the insanity is the expression.

The most rapid atrophy of muscles takes place in delirium acutum, whole groups of muscles wasting in an incredibly short time. There are recalled in this connection cases of typhomania (which, by the way, seems to be less common than formerly)—instances of large and powerful men in whom at the end of some days, and in spite of every effort to sustain nutrition, the atrophy was so great that, as an attendant once well expressed it, "the muscles seemed to have all melted away."

In various acute toxic insanities muscular atrophy may result from lesions of trophic centres, and in alcoholic dementia especially it is common from sclerotic degeneration of the motor cells of the anterior cornua of the spinal cord. In the diathetic insanities muscular atrophy is a not infrequent symptom. Thus, there is arthritic atrophy in cases with gout and rheumatism; atrophy from focal or disseminated lesions of nervous centres in syphilitic insanity; atrophy in cancerous or tuberculous cases from disease of joints or bones or deep-seated burrowing abscesses which evacuate pus, which passes into the sheaths of muscles and by long-continued contact excites fibrillary atrophy. In the scorbutic diathesis from changes in the blood and extensive intramuscular hemorrhages atrophy may result, just as it may be a sequel in post-febrile insanity from rupture, hemorrhage, and abscess in degenerated muscles. And in this connection it is apropos to call attention to the great frequency of deep and diffused abscesses among the insane from diathetic, toxic, traumatic, and other causes, and to suggest the early and thorough evacuation and antiseptic washing out of the same in order to avoid the possibility of muscular atrophy as well as other disagreeable sequels.

Incidentally it is here to be noted that inflammation of muscles, though a rare affection, is relatively frequent in rheumatic and syphilitic and in other forms of insanity. It may be due to accidental traumatic injuries or to toxic influences. It may have a chronic and subacute form, manifested by repeated lumbago, torticollis, and pain and soreness of the muscles of the extremities on slight exposure to cold or dampness or

on unusual fatigue. This myositis may also have an acute and severe course, followed by deep-seated abscesses, and then it may be mistaken for phlegmonous erysipelas or cellulitis. The skin over the inflamed muscle will be œdematous and red, and blood and serum will be effused on section; but pus will not be evacuated, but will gravitate diffusely in muscular sheaths, according to the position of the limb, and may finally become a cause of atrophy.

Again, muscular atrophy in general paresis and alcoholic dementia follows polyneuritis, just as it is the result of the multiple neuritis of the various toxic insanities. Space will permit only the passing mention of the common existence of muscular atrophies in idiocy, imbecility, and cretinous insanity. In senile dementia there is sometimes premature muscular atrophy with actual neuritic degenerations, and a point of practical clinical importance in these cases is that there is a corresponding cutaneous atrophy. Through muscular wasting the skin is in close apposition with bony prominences, and such is its tenuity that on slight manual pressure there is danger that extensive abrasions may arise.

Muscular atrophy may also be of traumatic origin. Through accidental falls or blows, such as seem more or less inevitable among the insane, there arise severe contusions, which may be attended with so much swelling and loss of motion as to suggest fracture at first. The patients from advice or choice remain in bed and inhibit all motion of the injured part, to avoid pain at first, but finally out of mere habit or delusion, and the result is atrophy.

Among demented, stuporous, and bedridden cases of insanity atrophy often comes from simple disuse. These supine and helpless patients when left to the natural course of muscular events sink into fixed attitudes of flexion and adduction, and in course of time loss of motor function and atrophy of muscles result. The prophylaxis of this form of atrophy is friction and passive movements of limbs and the avoidance of permanent postures in this class of patients.

Another disorder of the muscular system in insanity which is very common, and has a varied pathology, is tremor. These tremors may be coarse or fine, they may be partial or general, they may be constant or interrupted, they may be present only on intentional effort; and whatever may be their clinical character, they almost invariably cease during hours of repose.

In general paresis there are three kinds of tremor which are to be distinguished from ataxic disorder and from fibrillary twitchings of muscles. In the first place there is a fine and rapid tremor having a probable average of ten oscillations per second, which is present much of the time, though it may escape superficial inspection, and which exists independently of purposive muscular movements. It is found chiefly in advanced stages of general paresis, and is doubtless due to widespread organic lesions of nervous centres. The second kind of tremor is coarser and belongs rather to the class of intention tremors, or at least is most evident on intentional muscular efforts, and it will be readily observed as the patient extends the hands and separates the fingers. The third kind of tremor is still coarser than the one just mentioned. It may be described as a grossly exaggerated tremor, and, though it may not be positively and exclusively of psychic origin, it is apt to be most manifest in the hands of the patient during movements of great emotional excitement.

Space will not permit a discussion of the various tremors present in alcoholic insanity. They assume a variety of interesting forms, and when permanently present they are of unfavorable prognostic import, as pointing to disseminated organic lesions of cerebro-spinal nervous centres. The various toxic insanities

have tremors differing somewhat in type, that of hydrargyria being especially pronounced in character, though that of nicotinism may be almost equally well marked. One youth under my charge, who was insane from great excess in cigarette smoking, had a fine tremor which was almost constant, while in another case of like origin the tremor was notable only during movements requiring special co-ordination.

The insanity of auto-intoxications also may be accompanied by tremor increased under strong emotion or on intentional efforts.

In the tremor of senile dementia the head as well as the hands is often involved, and this is a symptom which augurs ill for the recovery of the patient.

There is another class of tremors found in the functional psychoses, and most frequently in debilitated, ill-nourished, or neurasthenic cases, due solely to the failure of cortical motor cells to furnish the physiological quantum of continuous efferent motor impulses, and a similar tremor from defect of cortical innervation may occasionally occur in very youthful subjects in the insanity of childhood and in states of arrested mental development. It is of interest to note that this tremor in some degree keeps pace with the general rhythm of psychic processes, and it will be found accordingly more rapid in mania than in melancholia. Emotional tremors so frequent in insanity are too well known to call for special description here.

Hastening on, with a mere allusion to the tremor of tabetic types of insanity, to the tremor of cases with paralysis agitans or with disseminated cerebro-spinal sclerosis, to the tremor of organic dementia with descending degeneration of the pyramidal tracts, and to the tremors of sudden brain anæmia from vasomotor spasm, there next comes under consideration a much grosser disorder of the muscular system known as contracture.

Contractures are so common among insane patients that a lengthy description of their familiar features is hardly necessary, and attention will be directed here more especially to their etiology. One of the most common causes of contracture in dementia, stupor, or melancholia is the fact that in these states the flexors act in excess of the extensors, and through delusion or entire lack of spontaneity on the part of patients their limbs remain in permanently flexed positions. Now, if no correction of this flexed posture habit is made it will not be long before the physician will be called upon to recognize the pathological fact that the muscles of limbs continuously flexed and disused undergo first shortening, then degenerative tissue changes, and finally permanent contractures. If the patient has been long bedridden the foot will be found flexed on the leg, the leg flexed on the thigh, and the thigh flexed on the abdomen, and sometimes nothing but a severe operation—anaesthesia, the free use of the tenotomy knife, and the overcoming of ankylosed joints—will relieve the contractures; so that "an ounce of prevention is worth more than a pound of cure" with these subjects whose physical condition often will not justify the severity of the operation necessary for their relief. Another familiar example in this same category is referable to the forearm group of muscles, and in this instance by permanent contracture of the digital flexors the finger tips are fairly buried in the palms of the hands and there is almost invariably a simultaneous forearm flexion. The posture habit of crossed knees sometimes causes contracture in a way not wholly parallel to the above, as there is superadded the influence of pressure partially interrupting circulation and nervous innervation.

The etiology of another class of contractures is to be sought in the central nervous system. In organic dementia the early and late rigidity of paralyzed limbs

is followed by structural contractures from descending degenerations of the motor tracts, and they occur likewise in syphilitic, alcoholic, or epileptic and paretic insanity, from disease of the pyramidal tracts, and it is probable that the permanent contractures of hysterical insanity are due to a like cause. In the above forms of insanity there are also exceptionally observed a variety of spastic conditions of the muscles due to sclerotic changes in the lateral columns of the cord. In alcoholic insanity also, as in other toxic forms, contracture may be the sequel of multiple neuritis. In idiocy contractures are very common as the result of early encephalitic processes. In rheumatic insanity contracture at times follows the arthritic affection, just as in general paresis it may be secondary to arthritis deformans.

Another muscular disorder which the alienist often encounters among his patients is spasm, which may be clonic or tonic, and which for want of a better term will here be extended to embrace a variety of allied affections common among the insane. One of the most notable forms of spasm is that which causes the familiar symptom of the grinding of the teeth, which may be thus almost completely worn away, and the tongue and buccal mucous membranes may be severely bitten, more especially in the final stage of general paresis. This is a bilateral masticatory spasm of muscles supplied by the motor branch of the trigeminal nerve. It is found also in phthisical insanity with basilar meningitis, in delirium acutum, in idiocy, in hemiplegic dementia, and in syphilitic insanity with basal gummata. It is well to know that there may be actual paralysis of this motor branch of the trigeminal nerve in the terminal stage of general paresis, and that the inability to masticate in these cases is due to this fact and is not merely ataxic in nature.

There are frequently observed, among the neurasthenic insane more especially, fibrillary spasms, which consist in the independent clonic action of the separate fibres or strands of muscles. These fibrillary spasms occur usually in the orbicular, facial, or forearm muscles and often recur at more or less rhythmic intervals of a few seconds or moments during all the waking hours of the day for weeks or months together. Their pathology is probably local irritation of cortical cells in motor areas representing the muscles affected, and it might be considered as so proven should they be reported in a case of insanity from trauma capitis with lesions of motor cortical regions and with spasmodic muscles exactly corresponding to our knowledge of the crossed innervation of the brain cortex, and of localization of motor centres.

Another kind of spasm of some interest, though of superficial importance, because usually artificially provoked in origin, is met with in patients under the tension of persistent delusions or emotions, as in melancholia attonita and like states. When such a subject is urged to speak or otherwise aroused, the only response may be a series of spasms of one or several muscles of the face, neck, or pharynx. The condition of these patients is one of extreme mental inhibition, and when it is suddenly interrupted there is a spasmodic liberation of motor impulses, chiefly in the regions of the mimic facial muscles. Permanent forms of unilateral convulsive tics of face and neck muscles are not infrequent and also bilateral spasms of clonic form, especially of the eyelids, as in facial habit chorea, only greatly exaggerated in character. Nictitation is more common than nystagmus. Typical blepharospasm may exist for weeks or months together.

A man insane from alcoholic excess came under my care with clonic unilateral spasm of the right sterno-cleido-mastoid accompanied by a loud inarticulate noise. The noisy part of this phenomenon was regarded as an instance of vocal-impulse tic engrafted

on a spasmodic muscular tic, as in my observation of the insane the conjunction of psychic tics and of convulsive tics occasionally occurs. Echolalia and coprolalia may coexist with this muscular disorder, the patient repeating what is spoken in his presence or uttering some profane or obscene word at the instant of the spasmodic movement. There are also slow rhythmic tics and a variety of athetoid movements in which the fingers move slowly or briskly even in the same case, according to the amount of emotion present. The sudden twitching of muscles or groups of muscles known as subsultus tendinum, which in its simple form is wont to occur on the verge of sleep, often becomes a very troublesome symptom among the insane, recurring throughout the day and preventing sleep at night, the patient being awakened with a spasmodic start almost like an electric shock.

Confirmed clonic spasm of the muscles supplied by the external branch of the spinal accessory nerve is sometimes found in hysterical and epileptic insanity, and other muscles of the neck and arm may become involved. Clonic spasm of the diaphragm is met with in hysterical and hypochondriacal cases very often, and in my observation it has occurred also as a persistent anteletal symptom in both organic dementia and general paresis. Clonic lingual spasm is not a very rare symptom in general paresis, and it may somewhat interfere with speech or mastication, the tongue sometimes being severely bitten.

The clonic spasmodic disorders of choreic insanity are to be named here also, though want of space will not permit their special description, but it is important to state the general principle that the younger the patient the more apt is the insanity to reveal itself through the medium of the muscular system, and it is safe to estimate that in the insanity of childhood disorders of the muscular system exist in seventy-five per cent. of all cases.

There is a whole chapter of spasmodic clonic affections in general paresis. Some of them occur during any of the stages without loss of consciousness, and others during the paretic seizures with loss of consciousness. In the latter case the clonic spasm begins usually in the face and extends to the arm and then to the leg. This customary order of protospasms is often interrupted in general paretic seizures, however, the spasms skipping from one side to another and from one muscle to another, in ocular, facial, brachial, and crural regions, in a most remarkable manner. There is no certainty in these seizures that the conjugate deviation of the eyes will be toward the side of the lesion. Nystagmoid motions often precede any other spasmodic ocular movements in these seizures.

The tonic spasms of insanity, in contradistinction to the clonic ones above described, are very numerous. One of the most common is spasm of the orbicularis palpebrarum, which may persist for days or weeks together. Tonic spasm of the sterno-cleido-mastoid and trapezius muscles is a common symptom, especially in its milder forms, usually spoken of by patients as stiff neck. Tonic œsophageal spasm and pharyngeal spasm are not very rare, and the latter in hysterical insanity may be so severe and continuous as to interfere seriously with the alimentation of the patient, and in these cases also œsophagismus and gastric spasms may cause obstinately repeated emesis. In ascending cases of general paresis these pharyngeal spasms may be very annoying. Laryngeal spasms also occur, and some years ago, in my article on "Laryngeal Hyperkineses," read before the New York Neurological Society, a case was recorded of laryngeal spasm continuous for two years as a premonitory symptom of general paresis, which finally terminated fatally in typical form. There are also to be enumerated here diaphragmatic

and abdominal spasm, intestinal and gastric spasm, phantom tumors from muscular spasm, prolonged chasmus and aphthongia.

Strabismus in its various forms must also receive a word of notice. It is common in all types of insanity with severe organic brain lesions, and it is my impression that permanent divergent squint especially is of unfavorable prognostic import.

Cramps of all kinds are among the muscular anomalies to be noticed, the gastrocnemius being perhaps the most frequent site of the disorder, which may be very painful or a persistent cause of insomnia, especially in neurasthenic and alcoholic insanity. There are, moreover, in alcoholic and in other toxic cases, spastic states of the muscles of the legs, more particularly due to the sclerotic degenerations of the spinal cord. There are also the various cataleptoid and tetanoid states of muscles, requiring more space for description than can be accorded in the brief limits of this article. Suffice it to mention the tetanoid rigidity of muscles in post-hemiplegic insanity, the tonic and spasmodic pedal extensions in alcoholic dementia, the catalepsia spuria of hysterical and pubescent insanity, the "flexibilitas cerea" of stuporous and epileptic cases, the tetanoid seizures of the final stage of general paresis, and the saltatory cramps of acute delirious mania.

To complete this pathological array of symptoms of the voluntary muscular system in insanity, there remains finally to be described the group of pareses and paralyses. The differential diagnosis of these pareses and paralyses is a complete test of the physician's knowledge of neurological pathology, as the utmost skill is required to determine whether the source of the muscular disorder is in lesions of cortical motor regions, efferent conducting fibres, internal capsule, pyramidal decussation, spinal motor cells, anterior nerve roots, or in the spinal nerves or in their peripheral distributions. These muscular disorders may occur in syphilitic dementia at any of the points mentioned. In arrested mental development they arise from encephalitis; in general paresis they are chiefly cortical; in all the toxic insanities they may proceed from spinal cellular degenerations or from peripheral neuritis; in organic dementia from thrombotic or embolic softening and internal capsular lesions; in senile dementia from vascular atheroma and atrophy of brain cortex; and in alcoholic dementia from sclerotic interruptions of the fibres of the pyramidal tracts or from the pressure caused by subarachnoid or intraventricular effusions; and they will be found to be sometimes functional, or at least of undeterminable morbid anatomy.

These pareses and paralyses may assume every variety of form, such as hemiplegia, paraplegia, crural or brachial monoplegia, or loss of motion in facial, ocular, orbicular, and sphincter muscles.

The paralysis of muscles supplied by cranial nerves is especially common in syphilitic dementia, the monoplegias are frequent in organic dementia, the paraplegias are wont to occur in hysterical and alcoholic insanity, while hemiplegia appears in epileptic dementia; and a combination of these affections is to be witnessed in the various types of general paresis. It will be found on closer study, however, that the paralyses of general paresis are more apparent than real—that the muscles have not lost power to act singly but in co-ordination with one another, and that it is ataxia and not true paralysis which gives the impression of loss of voluntary motion. The disorder of the muscular mechanism of speech in general paresis is also essentially ataxic, proceeding first from disease of cortical cells, and later from bulbar lesions of the facial and hypoglossal nuclei and of nerves of innervation of lips, tongue, and vocal organs. In typical paresis the

gait also is ataxic throughout, but in ascending cases it is tabetic at an early stage, and in occasional instances of sclerotic lesions of the lateral columns the gait becomes markedly spastic, just as in alcoholic dementia. It is possible in the same case of general paresis to have these three typical anomalies of locomotion illustrated—first, the true paretic gait from disease of cortical motor cells; second, the tabetic gait from lesions of the posterior spinal columns; and third, the spastic gait from sclerosis of lateral columns. The clinical fact, however, is that in fully developed general paresis the defects of gait vary considerably from time to time, and bear an intimate relation to the nature and number of the convulsive seizures. There are to be mentioned here, also, certain remarkable cases of insanity, in which there is static ataxia as well as complete locomotor inco-ordination. These patients cannot stand or walk alone, and on trying to do so they have violent random movements of arms and legs and of head, neck, and body, and if not firmly held by the hands of nurses they are apt to suffer severe falls or injuries.

The pareses of insanity have a diversified etiology. They may spring from failure of exhausted cortical centres to evolve sufficient motor impulses, or of efferent nerve fibres to conduct them, or they may be the sole result of mental inhibition in melancholic states with great mental tension. They appear in various forms of insanity, and may affect any or all of the muscles. They are less apt to escape diagnosis in the extremities than in some other muscles, and attention is directed here to their frequency in the levator and tensor palati muscles, in the pharyngeal constrictors, in the œsophageal muscles, and in the tensors of the vocal cords. Prolapsed or deviated palate, various forms of dysphagia, and marked changes in vocal tone are very common from this cause. In hypochondriacal and neurasthenic insanity these pareses are often the outcome of delusion, and may be very persistent, affecting, as a rule, only one extremity; but in hysterical insanity they may be interchangeable, involving one or both upper or lower limbs, and in almost any imaginable order. The paresis of the muscular organs of speech is occasionally very pronounced in neurasthenic cases and in states of brain exhaustion from overwork, and the ignorance of this fact has led many a physician into gross error in mistaking these functional speech defects for those which spring from organic brain lesions. There may be paresis of speech muscles in the hypochondriacal insane, not alone from strong prepossession by an idea or an emotion, but from force of imitation also, just as stuttering may be likewise acquired by sane persons. Muscular disorders from force of imitation are to be witnessed, especially in epileptic insanity, and St. Vitus' dance, tarantulum, and spasmodic muscular disturbances have always been prominent phenomena of historic epidemics of insanity. Again, there are intention pareses as well as intention tremors among the insane.

There remain to be brought to notice a few functional abnormalities and some sensory disorders of the muscular system. One of the decided anomalies in muscular functions is the inco-ordination so common in many forms of insanity. It is by no means confined to tabetic, paretic, senile, or toxic cases of mental disease, in which well-known cerebro-spinal lesions may act causatively. Inco-ordination in the functional psychoses may be associated with cortical anæmia from vasomotor spasm, or with stomachal, aural, or cardiac vertigo, or with powerful mental inhibition, or with loss of the muscular sense. The symptom is none the less real, however uncertain its etiopathology may be. This inco-ordination may show itself in neurasthenic insanity, for instance, in gait, speech, handwriting, or any of the highly specialized acts. It is

also to be seen even as static ataxia, as a modified form of Romberg's symptom, or it may present itself as pseudo-astasia abasia. Another functional change in muscles is their abnormal reaction to external stimuli. The mechanical muscular excitability may be shown by slight blows over muscles to be sometimes increased and at other times diminished in epileptic, hysterical, and parietic cases; and in phthisical insanity a slight tap on the body of muscles may provoke a tonic contraction for a very perceptible period. In the acute stages of certain forms of mental disease the reflex irritability may be increased to the degree of general convulsibility. The electro-muscular reactions are not infrequently abnormal in insanity, both as regards the use of the faradic and of the galvanic current, and the reaction of degeneration is occasionally to be witnessed. The electro-muscular contractility is diminished in idiocy and in profound dementia, and the electro-muscular sensibility may be lost in hysterical and in some other forms of insanity.

In health the muscles of the body in repose are not completely relaxed, but they are in a permanent state of tonicity, which is known as the "tonus muscularis."

In insanity this physiological muscular tone may be increased, diminished, or lost.

As a general rule, the tonus muscularis is increased in states of exaltation and diminished in states of depression, and in deep melancholy and stupor and in the final stage of general paresis it is lost. The lack of all expression in the face of some insane patients is due partly to this absence of normal tone of facial muscles.

A careful study of the muscular system among the insane will often reveal to the expert eye certain permanent signs of neurotic degeneration. These muscular stigmata degenerationis consist in asymmetrical lateral development of the muscles of the face, limbs, or body. In addition to this inequality in the size of muscles, there is often inequality in the innervation of the same on the two sides of the body, and this disparity in facial muscles causes an asymmetry of expression characteristic of the insane physiognomy.

A final abnormality in the functional activity of the whole voluntary muscular system may be termed the automatism of insanity. The largely reflex and mechanical nature of the semeiology of mental disease has never yet been sufficiently expounded. Additional light would be thrown on that which is to be said did space here permit some explanation of the psychic automatism of insanity, but this must be reserved for a separate article, and muscular automatism alone will be here briefly noticed.

The fixed attitudes of the demented in whom, through predominant action of flexor and pronator groups of muscles, the extremities are flexed, the body inclined, and the head bent forward on the chest, and other characteristic postures retained for weeks, months, or years, at first possibly in obedience to delusions but finally mechanically, constitute permanent examples of passive automatism. This passivity may be so great that positively no movement of hand, foot, or head is spontaneously initiated, and the passive automatism becomes absolute. On the other hand, the repetition of the selfsame aimless movements for months and years together is characteristic of active automatism. The head, body, or limbs may be constantly moved to and fro, or from side to side, or rotated, during all the waking hours, the monotonous motions ceasing only during sleep, and reappearing at the earliest moment of awakening, just as in the automatism of idiocy. These automatic acts may be simple, complicated, or rhythmical, and they exist in great variety. In the first instance they may originate in some motive or delusion, but eventually they become insignificant of any idea, and simply represent

the automatic escape through motor channels of such nervous energy as is daily evolved in cerebro-spinal centres. The constant swinging of the foot with crossed knees, the incessant friction of some part of the clothing, the stationary rocking from one foot to another, the shuffling in one position, walking in a circle, stereotyped movements of the head with humming or strange noises, rhythmical stroking of the head or face, rubbing of the hands together, measured time-beating with hand or foot—all these are instances of active automatism. In a somewhat unique case under my observation, the automatic rotary friction of one thumb nail on the other had resulted in epithelial hypertrophy, so that the nail had attained several times its natural size both in length and thickness. The most complicated automatic acts form a part of the symptomatology of epileptic insanity. In fact, post-epileptic automatism reveals an astonishing variety of highly co-ordinated and even most skilful acts unconsciously performed. In mania, also, with acute exacerbations and entire loss of mental inhibition, both acts and ideation become largely automatic, and the efferent peripheral and sensorial stimuli play upon the central psychomotor mechanism of the patient as upon an instrument. All ideas and feelings tend to issue at once through muscular channels, and by intense cortical irritation tumultuous emotions are spasmodically liberated and are expressed in incoherent and disorderly movements or in automatic laughing and crying. In some demented and with insane children the inco-ordinate and aimless muscular movements are more nearly to be compared with those which arise automatically during the early months of infancy. The ceaseless and purposeless muscular activity of certain idiots and imbeciles is also nearly allied to the spontaneous hyperkinesis of infancy.

The sensory disorders of the muscular system in insanity must be briefly noticed.

There is physiological proof that man has six senses. The muscular or kinæsthetic sense, like the others, has cortical representation, possibly in Rolandic areas, as it conveys to consciousness impressions of the resistance of external objects, and of the muscular effort essential to overcome the resistance, and also of the relative position of the limbs in space. The loss of the kinæsthetic sense in general paresis accounts in some cases for the pseudo-astasia abasia, and also for the fact that paretics often fail to know the position of their arms or legs in bed, and that they cannot estimate the force required to lift things. In hysterical insanity with paralysis the muscular sense is lost, and it is generally impaired in epileptic insanity.

Muscular anæsthesia is not infrequent in epileptic and parietic cases, and muscular analgesia is so marked among some insane patients that the infliction of injuries and even the most extensive self-mutilations may be painless.

Muscular hyperæsthesia is also to be found in neurasthenic insanity, causing exaggerated muscular reflexes and giving rise to delusions as to the size of the body and limbs. It also accounts in some acutely hypochondriacal and melancholic cases for the sense of weight and soreness of the muscles. The extreme restlessness and the "anxietas tibiæ" of melancholia agitata is in part due to muscular hyperæsthesia.

Myalgia in its various forms is very common among the insane, who complain of stiffness, soreness, and pains in the muscles of the arms, legs, neck, and back.

Lumbago and pleurodynia are not so common as temporal, frontal, and occipital muscular pain, and the nuchal muscles of all others seem to be the most frequent seat of this sensory disorder. In occasional cases of hypochondriacal insanity myodinia is the most constant symptom.

In conclusion, there remain to be mentioned the

disorders of the involuntary muscular system of organic life.

The pathological variations of vasomotor innervation of the muscular coat of arteries in insanity account for many important symptoms. Thus there may be increased or diminished intravascular blood-pressure and many rhythmic variations in pulse character, best determined by sphygmographic tracings, as described in my paper on "The Pulse in Insanity," read before the American Neurological Society last year.

The tonic spasm of the arterial muscular coat is most marked in melancholia and in certain phases of epileptic and paretic insanity. The increased "turgor vitalis" of mania and the angioparetic symptoms of various forms of insanity are to be mentioned in this connection.

According to recent reports of careful post-mortem examinations in one hundred and twenty-three cases of dementia by Wulff—a German investigator—the heart, as the most important muscle in the body, is diminished in total weight in chronic insanity.

It is well known that the muscular structures of the intestinal tract, of the bladder, of the rectum, and of the reproductive organs are innervated in a reflex way by spinal centres, and that they are all under a certain voluntary control through nervous fibres, which place the spinal reflex centres in connection with cortical inhibitory centres.

Irritative or destructive lesions of these centres or nerve fibres in insanity may occasion a great variety of muscular disorders in the parts above named. Thus, through paresis of the intestinal muscular coat arises obstinate constipation and troublesome and even dangerous impaction of fecal masses in the large intestine. Or there may be spastic muscular conditions and greatly increased peristalsis, with pseudo-diarrhoea and pseudo-dysentery and borborygmi and false tympanites, through spasm of abdominal muscles. In some cases of insanity there is spasmodic retention or evacuation of the bladder or rectum, and in other cases paralysis of the same and involuntary and even unconscious escape of their contents, as in general paresis and other forms. The delusions of the insane, so often referable, especially in women, to the reproductive organs, may in some instances be connected with real disorders of the muscular structures of these parts.

To make an exhaustive study of all the symptoms which occur in insanity from disorders of the unstriated muscular system of internal organs would far exceed the intended limits of this article.

The whole question of muscular reflexes and pupillary reactions in insanity, though naturally a part of our subject, has been purposely omitted, because it has already been adequately treated by other writers.

The final summation of conclusions deemed to be legitimately drawn from this paper is as follows:

The organic lesions of the cortical, bulbar, or spinal centres and of the peripheral nerves in insanity cause frequent disorders of the muscular system.

Functional diseases of cerebro-spinal nerve centres in insanity are likewise attended by functional muscular disorders.

The incoherence, excitement, and general psychic disorder of insanity are reflected directly through the voluntary muscular system.

The deep derangement of vital functions and of internal organs in insanity is accompanied by disorders of the muscular system of organic life.

All these muscular disorders constitute a most essential part of the somatic symptomatology of insanity, and as they are of the greatest value both in the diagnosis and prognosis of mental disease they deserve a more complete clinical study than they have hitherto received.

THE DAWN OF REASON.

By JAMES WEIR, JR., M.D.,

OWENSBORO, KY.

SOME animals, exceedingly low in the scale of life, give evidences of the possession of a ratiocinative faculty, ay, of a reasoning faculty, the same in kind though not in degree as that possessed by man. The following experiment, one that I have performed time and again, will demonstrate this. The natural habitat or dwelling-place of *æthalia*, a minute, microscopic animalcule of very low organization, is sawdust. If these creatures be taken from sawdust and placed in a watch crystal in which there is water, they will confine themselves to it; but if the glass be placed on sawdust they will leave it, crawling over its sides in order to get into more congenial surroundings—the sawdust. This shows conclusively that they recognize the dust through the transparent glass, and that they also remember and regard it as a more desirable home. Memory, conscious determination, and the fundamental principles of reason are, in this instance, clearly demonstrated. On one occasion, while examining a water louse through a large low-power lens, I saw it approach a polyp, gnaw off one of its buds, and then retreat to some distance, where it hid itself behind a particle of mud and proceeded to devour its victim. After a while it left its sheltering lump of mud and again swam to the polyp, which it immediately deprived of another of its young. It then swam back to the same little mud heap and there resumed its meal. This louse showed, in this instance, that it knew that the polyp was good for food; that it remembered the road to and from its source of food supply; and that to avoid interruption it hid itself while eating.

A wasp, of the variety commonly called "mud-dauber," last summer built her nest on the ceiling of my room in one corner. The windows of this room remained open night and day during the hot summer months, so her nest was easy of access. One day, while the wasp was busy about her home, I closed all of the windows and awaited developments. At length she flew toward a window, against which she landed with a thump which for a moment or two completely dazed her. The wasp soon discovered that she was barred from the outer world by some transparent, translucent substance; she then proceeded on a voyage of discovery, flying around the room and searching here and there and everywhere for an exit. She finally found a small hole in the window casing which communicated with the outside; through this she made her escape from the room. Upon opening the window I saw her examining the passage through which she had come, going through it repeatedly. She finally flew away, but shortly returned with a pellet of mud. Notwithstanding the fact that all of the windows were then open, the wasp went at once to the hole in the casing through which she made her way into the room and thence to her nest on the ceiling. She never again, so far as I was able to ascertain, made an exit or an entrance through the windows, but always made use of the hole in the casing. This little creature undoubtedly gave unmistakable evidences of ratiocination; she found that a transparent barrier had been placed in her way—a barrier so translucent and transparent that she could not see it until she actually felt it. She therefore concluded that she would never again risk injury by flying through the windows. What is most remarkable about this instance is that this insect derived her knowledge from a single experience and at once profited thereby. All wasps, however, are not so intelligent as was the one just mentioned, for it required several lessons to teach a ground wasp some-

thing similar. A ground wasp once built her nest beneath the brick pavement in front of my door. The entrance of the nest was situated in the little sulcus or ditch between two bricks. While the wasp was absent I stopped the entrance with a pellet of paper, and when the little housekeeper returned she was nonplussed for a moment or two, when she discovered that her doorway had been closed. The wasp, after examining the pellet of paper, seized it with her jaws and tried to pull it away; but, since she stood on a brick and pulled backward (toward herself), the edge of the brick interposed and she could not dislodge the obstacle. Finally, the wasp got down into the little gully between the two bricks and pulled the pellet away from the opening of the nest without any further trouble. Three times I performed the experiment, the wasp going through like performances each time. At the fourth time, however, she went at once into the little space between the bricks and then removed the wad of paper without difficulty. I stopped the hole five or six times after this, but she had learned her lesson; she always got into the sulcus between the bricks before attempting to remove the paper. She had discovered the fact that she could not remove it when she stood upon the surfaces of the bricks, owing to the interposition of their sides, and that she could drag it away if she got down into the little ditch and pulled the paper in a direction where nothing opposed.

Fleas have, comparatively speaking, highly developed minds. There are many people alive to-day probably who saw the trained fleas which were on exhibition in the large cities of the United States some thirty or forty years ago. These insects had been taught to go through certain evolutions at the command or signal of their owner and trainer. The mere fact that they possessed memory enough to learn, retain, and remember their lessons is not proof positive of reason; but the fact of their having restrained their natural tendency and desire to escape when they could so easily gratify such a desire or tendency is a potent factor in an argument for their possession of the ratiocinative faculty. Their teacher explained that he "brought them to reason" by keeping them at first in a glass vessel, where they jumped and bumped their heads to no purpose against the transparent walls of their prison. Thus their vaulting ambition was held in check and they learned to reason from cause and effect.

On one occasion I saw a flea show an evident gratification in a bit of malicious sport. I was observing a sleeping flea among the short hairs on a dog's leg, when another flea made her appearance beneath the lens. This flea soon discovered her sleeping sister, stopped short, and seemed to be in deep thought for a second or so. She then crept slowly up to within an inch of the recumbent flea, gave a little bound, and landed squarely upon her back. She clasped the astonished slumberer in her hindlegs and proceeded to vigorously "tousle her hair" with her forelegs; then, springing to one side, she hurried away, closely pursued by the thoroughly aroused and evidently angry victim of her sport, and was soon lost to sight among the long hairs of the dog's back. I have seen like scenes time and again, in which human beings instead of fleas were the actors.

When we come to study the higher animals, evidences of their possession of reason crowd thick and fast upon us, and were I so minded, I could fill ream upon ream of paper with authentic anecdotes of their ratiocinative powers. I purpose, however, to give instances of ratiocination in animals that have occurred under my own observation or that have been witnessed by people whom I know and for whose probity and truthfulness I can vouch.

The ant is generally classed among the lower animals by observers, but a careful study of its cerebral anatomy and of its psychology leads me to place it among the higher animals, especially in point of mentality. When we take into consideration the fact that an ant's brain has gray matter analogous to the gray matter found in the cortex of the human brain, we should not feel surprised when we find striking evidences of ratiocination in these little creatures. The better creatures are able to communicate ideation or thought, the stronger and more frequent are the evidences of their possession of reason. Ants can undoubtedly communicate; how and in what manner, it is not generally agreed. Some time ago I crushed an ant in the path usually taken by the inhabitants of a nest (which was situated in a hollow tree) in their journeys to and fro. A soldier ant came along presently, and, smelling the blood of her murdered companion, was seized with a sudden terror and fled away into the nest. She soon returned, however, with thirteen other soldier ants, and made a careful examination of the body and its surroundings. Her companions also examined the corpse, and, having satisfied themselves that their comrade was dead and that her murderer was not to be found, returned to the nest. Soon afterward a large worker ant, guarded by two soldier ants, came out, and, proceeding to the body, picked it up, carried it down the tree and away beneath the grass, where I lost sight of them. In this instance there is every evidence of complex reasoning; the discoverer of the murder hurried away into the nest, where she gave the alarm; the police of the community, the soldier ants, went immediately to the scene of the tragedy, made an examination, and then returned and gave in their report; the undertaker, in the shape of the large worker ant, then went out, got the body, carried it away and buried it: the two soldier ants followed the body to the grave, in order to protect it from cannibal ants.

It has been my good fortune to have witnessed several pitched battles between large bodies of ants. In a battle between some black ants and some yellow antagonists of another species, I saw many evidences of intelligent communication. The yellow ants had a commissariat and an ambulance corps, and I frequently saw them drop to the rear during the battle and partake of refreshments or have their wounds attended to. The blacks, which composed the attacking army, were in light marching order and had neither of these conveniences and necessary adjuncts. The yellow ants frequently sent back to their village for reinforcements; those of them that had been out on hunting expeditions when the battle was joined were notified as soon as they arrived at the nest, and immediately hurried out to join in the fray. The blacks had discovered a herd of aphides belonging to the yellows, and had sought to surprise the guards and steal the herd: hence the battle. I am glad to report that the black horde was defeated by the brave yellow warriors and had to decamp, leaving many of its number dead upon the field of battle. On another occasion I saw an army of red ants besieging a colony of small black ants. The object of the red ants was the theft of the pupæ or young of the black ants. These pupæ they take to their own nests and rear as slaves, the enslaved ants to all appearances becoming entirely satisfied with their condition and working for their masters willingly and without demur. The besieged ants evinced a high degree of reason and forethought, for, as soon as the presence of the besiegers was noticed, strong guards were posted in all of the approaches to the nest, both front and rear. The red ants sent a detachment to surprise the colony from the rear, but they found that surprise was impossible, for they were met by a strong party of their

gallant foes, which vigorously opposed them. The red ants were, however, eventually victorious and sacked the town, carrying away with them a large number of pupæ or young. I cheerfully bear witness to the fact that the great naturalist, Huber, was correct in his description of his experiment with these black slaves and their masters. Like Huber, I put some red ants into a glass jar in which I placed an abundance of food. Notwithstanding the fact that this food was of easy access, being, in fact, immediately beneath their jaws, they would not touch it. I then placed a black slave in the jar; she at once went to her masters, and, after thoroughly cleansing them with her tongue, gave them food, of which they ravenously partook. These red ants would have starved to death in the midst of plenty if they had been left to themselves. So utterly subservient had they become to the ministrations of their slaves that they had even lost the faculty of feeding themselves! Here we have an example of degeneration in the mentality of animals, incident to the enervating influence of slavery. Sir John Lubbock's remarks anent the four genera of slave-making ants are so interesting that I may be pardoned for introducing them.

Says he: "These four genera" [*formica sanguinea*, *polyergus*, *strongylognathus*, and *anergates*] "offer us every gradation from lawless violence to contemptible parasitism. *Formica sanguinea*, which may be assumed to have comparatively recently taken to slave-making, has not as yet been materially affected.

"*Polyergus*, on the contrary, already illustrates the lowering tendency of slavery. They have lost their knowledge of art, their natural affection for their young, and even the instinct of feeding! They are, however, bold and powerful marauders.

"In *strongylognathus* the enervating influence of slavery has gone further, and told even on the bodily strength. They are no longer able to capture their slaves in fair and open warfare. Still, they retain a semblance of authority, and when aroused will fight bravely, though in vain.

"In *anergates*, finally, we come to the last scene of this sad history. We may safely conclude that in distant times their ancestors lived, as so many ants do now, partly by hunting, partly on honey; that by degrees they became bold marauders, and gradually took to keeping slaves; that for a time they maintained their strength and agility, though losing by degrees their real independence, their arts, and many of their instincts; that gradually even their bodily force dwindled away under the enervating influence to which they had subjected themselves, until they sank to their present degraded condition—weak in body and mind, few in numbers, and apparently nearly extinct, the miserable representatives of far superior ancestors, maintaining a precarious existence as contemptible parasites of their former slaves."

During the summer of 1887 I spent several weeks in New Mexico, and while there had the great good fortune to discover a colony of honey-making ants. I found this colony in a little valley debouching out of Nuerfuanos Park, a government reservation, if I remember correctly, at that time. I made a very careful study of the habits of these interesting little creatures, and witnessed many evidences of true ratiocination in their mental operations. In order to make clear one or two instances in which they evinced true reason, a short description of this colony and its inhabitants will be necessary. The nest was situated on the sandy shore of a little creek, and was a perfect square of three or four feet, from which all grass, weeds, etc., had been carefully removed. Around three sides of this square, viz., north, east, and west, a column of black soldier ants continually patrolled night and day. Near the southeast corner of this open space the en-

trance to the nest was situated. The south side of the square was not guarded, but was left open for the entrance and exit of the hundreds of dark yellow workers, which were always engaged in bringing food to the village. This food they carried to the centre of the square and then deposited. No sooner was it put down than it was seized by black workers, which then carried it into the nest. At no time did I ever see a black worker bringing in food to the centre of the square, nor did I ever see a yellow worker carrying food into the nest; the blacks and the yellows never interfered with one another's particular duties. To test the reasoning powers of these ants, I partially disabled a centipede and threw it into the square a short distance from the patrol line. For a moment or so the line was broken by the warriors hurrying out to do battle with the squirming intruder. But only for a moment, for orders were issued by some one in authority; the line was re-established, though somewhat thinned by absent soldiers; a messenger was dispatched to headquarters and reinforcements were sent out, and soon the line was as strong as ever, though hundreds of soldiers were battling with the centipede. This latter animal was soon killed and its body removed piecemeal by yellow workers, which carried it far outside the boundaries of the square. Again, with my hunting knife I dug a deep trench across the border of one side of the square. The ants seemed dazed at first, but rapidly adapted themselves to their new surroundings. They extended their patrol line until it embraced the entire trench; then a countless horde of yellow workers went to work, and in a day's time filled up the trench level with the surrounding surface. The patrol was then established along the old line as though nothing had occurred to interrupt the ordinary routine of the colony. Before leaving the valley I dug up the nest and examined the peculiar individuals whose enforced habits give these interesting ants the name of "honey-makers." Each one of these curious creatures was confined in a separate cell, the entrance to which was very small. Here they lived in total seclusion, being fed by the black workers with pollen, the nectar of flowers, tender herbs, etc. They had no anal orifices, these passages having been artificially obliterated, I am convinced, by the other ants, which probably bit them, thus producing an inflammation which resulted in the growing together of the parts. These imprisoned honey-makers were merely animated bags of honey and were kept solely for the purpose of furnishing a never-failing supply of sweet and wholesome food. I tasted the honey and found it delicious; its flavor was distinctly winy and aromatic.

When we come to examine the mentality of the higher animals, such as the dog, the cat, the horse, the monkey, etc., we find that the evidences of ratiocination increase and become stronger as we approach the highest of the higher animals—man. Yet in the very lowest of the lower animals, the germs, the fundamental principles of true reason are in evidence; and the more we study the habits of these creatures and place ourselves as far as is possible on their levels, the more must we become convinced that instinct, while it does undoubtedly account for the greater portion of the psychical manifestations to be observed in the lower animals, does not, by any manner of means, account for all. Reason puts in an appearance very low, indeed, in the scale of animal life.

Retro-Pharyngeal Abscess.—Dr. Ambler (*Cleveland Med. Gazette*, March, 1896) says this affection is more commonly met with in children than in adult life, and when occurring in the former is generally associated with the strumous diathesis.

ON THE VALUE OF THE OPHTHALMOSCOPE AS AN AID TO THE DIAGNOSIS OF CEREBRAL DISEASE IN PURULENT AFFECTIONS OF THE MIDDLE EAR.¹

By THOMAS R. POOLEY, M.D.,

NEW YORK.

THE purpose of this paper is briefly to consider the value of the ophthalmoscope as an aid in the diagnosis of those cerebral complications which occur in purulent affections of the middle ear. It has been thought by the writer that to discuss this subject in such a society as this, largely made up of those who have not made use of the ophthalmoscope in their researches, might be of some service in calling their attention to an additional factor in determining whether cerebral implications may be present, and induce those who do not use this instrument to add a knowledge of its use to their accomplishments or refer their patients to an oculist for examination.

It is only within recent years that the importance of examining the fundus oculi in cerebral affections has attracted attention. Dr. Kipp, of Newark, was the first to call attention to the value and importance of such examination in the class of cases we are considering, and probably deserves, as Dr. Knapp says, the priority, although it would appear that several publications appeared about the same time; that of Albutt² was the first, in which he reported two cases of otitis media purulenta with optic neuritis, in which recovery took place. Dr. Kipp's³ paper was published some time after, in which he reported two cases of optic neuritis, in otitis media purulenta, in which recovery took place. Following these papers, Zaufall⁴ also recorded the case of a student, aged sixteen, with purulent otitis media and optic neuritis, which latter condition was observed to recede rapidly after the mastoid was opened, and the patient made a good recovery. Since these cases, which are cited only to bring out the names of those to whom belongs the credit of first calling the attention of the profession to them, many others have been published and the value of their observations thus confirmed. It is not my intention, however, even to attempt an enumeration of the papers which have been published on this subject, or of the cases of otitis media purulenta and its complications in which optic neuritis has been observed. It will suffice for my purpose to enumerate some of them and to report a single case of my own.

In 1883, Dr. J. A. Andrews read a most interesting paper on this subject before the American Otological Society, which, like all other communications from his pen, deals with the subject in the most comprehensive and masterly manner. He reports four cases, and, as they embrace all that is essential in the observations of those who wrote before, I will briefly refer to three of them.

CASE I.—Otitis media purulenta chronica, abscess of middle lobe of cerebrum. Death. This patient, aged twenty-four, had had otorrhœa on both sides since an attack of scarlet fever when twelve years old. Ten years thereafter pain developed suddenly in the right ear and corresponding side of head. During the night he vomited. Next day vomiting continued and he was dizzy. His physician's attention was attracted to the right eye, because of pain referred to it. Temperature, 103° F.; pulse, 130; respiration, 30. When

seen by Andrews three days later, he was conscious and talked intelligently. Right ear, hearing for watch and voice very much impaired, slight purulent discharge, small perforation in antero-inferior part of membrana tympani, swelling of wall of auditory canal; left ear, no active disease. Double optic neuritis. Right eye, counts fingers at 6'; left eye, vision, $\frac{2}{10}$. The patient died four days later in coma. No paralysis, no convulsions. At the autopsy an encapsulated abscess of the middle lobe of the cerebrum was found, extending from the tympanic portion of the Glaserian fissure outward into the external auditory canal for four millimetres, but not involving the ossicles. The bone was ulcerated. The communication with the brain was made at this point through a small fissure in the centre of the ulcerated bone. The dura over the diseased bone was also ulcerated and separated from the same by foul pus. The pia was congested. The middle and anterior fossæ contained pus. The brain was normal in consistence. The sinuses and inner ear were normal. These conditions refer to the right side of the brain; the left was normal.

CASE II.—Chronic purulent otitis media, optic neuritis, phlebitis of the right lateral sinus, meningitis of the convexity. Death. The patient, aged forty-two, had had otorrhœa for eight years, which had not been treated. Three years ago there seems to have been an acute exacerbation and he was treated for inflammation of the brain, but his ears received no attention. He said he had enjoyed good health since, but he had had, since the attack referred to, slight headaches. When seen by Andrews he had been confined to the house for two weeks, was very irritable and had severe pains in the head, sometimes diffused, at times referred to the right side. There had been no paralysis nor convulsions, but he had vomited during the first week of his present attack. For the first two days of attack he had illusions and delirium. Temperature had not been above 100.5° F. On the occasion of Andrew's first visit there was severe diffuse pain in the head, purulent discharge from the right ear, removal of which showed the bottom of the canal filled with granulation tissue. Right optic neuritis; left disc hazy; veins large and dark colored but not tortuous. Right vision, $\frac{2}{10}$; left vision, $\frac{2}{10}$. There was intensely sensitive induration extending in the course of the right jugular. He was under Andrews' care five days. The third day the right mastoid was opened with temporary relief, but he died on the fifth day in coma under the usual symptoms of sinus thrombosis. At the autopsy phlebitis of the right superior petrosal and lateral sinus was found. The right internal jugular contained a disintegrated thrombus. The dura covering the tegmen tympani and adjacent bone was congested and showed points of hemorrhage. There was purulent meningitis of the convexity of the cerebral hemisphere and the upper surface of the cerebellum, most abundant on the right side.

CASE III.—Otitis media purulenta chronica, meningitis, optic neuritis. Recovery. Patient, aged nineteen, had otorrhœa of left side for eighteen months. The discharge was profuse until about one week before he was seen by Andrews, when it became scanty. He came under his care six days after threatening symptoms began. The left ear contained a large polypus springing from the superior surface of auditory canal at the junction of its bony and cartilaginous part. Removal of the polypus showed the bone beneath exposed and rough. There were also two polypi springing from the tympanic cavity, which revealed pulsation at the bottom of the canal. After repeated efforts air was blown in the membrane corresponding to the point where pulsation was noted, but there was a perforation which could not be seen owing to swelling in the canal. The left membrana

¹ Read before the American Laryngological, Rhinological, and Otological Society, April 17, 1896.

⁴ Wiener Medical Press, 1881, No. 46, p. 1,452.

tympani was incised, the mastoid red and painful. Severe headache was general, but at times more severe on the left side and in the forehead. Temperature, 101° F.; pulse, 85. The patient was restless and vomited. Left eye, marked optic neuritis; right eye, retinal veins enlarged, disc very red but not œdematous. There was no other change in the fundus. Incision over the mastoid showed the bone inflamed but firm.

Thirty-six hours later the mastoid was opened by trephine. A small amount of blood and a trace of pus escaped. The cortical plate was thick; free communication between the opening in the mastoid and auditory was established and there was immediate improvement. There was from this time on a continuous improvement, loss of pain, lowering of temperature, and free discharge from the mastoid. The eyes were not examined the day following the operation, but on the morning of the fourth day thereafter. The left disc was less œdematous, the veins were not so full or dark looking, but the improvement was not striking. The patient was under Dr. Andrews' care for about two and one-half months. At the expiration of this time the left optic disc was hyperæmic, and the veins were much smaller than when last examined, about two weeks previous. The opening in the mastoid was closed, but there was still discharge from the ear; the right nerve was somewhat obscured.

Three months later the patient returned. The discharge had ceased. The left disc appeared to be normal and the right slightly hyperæmic. Right vision, $\frac{20}{20}$; left vision, $\frac{20}{20}$; right vision field normal, left vision field contracted.

The patient was seen again one year after the attack. There was no abnormal change in either fundus, but the visual field of the left eye, therefore on the same side as the affected ear, was slightly contracted.

In this case the diagnosis of cerebral complication was believed to have been confirmed by the ophthalmoscopic examination.

Before reporting my own case I wish briefly to report one published by Dr. C. J. Kipp,¹ of Newark, because of its great interest as demonstrating the value of repeated examinations of the eye with the ophthalmoscope in cases of otitis media purulenta, and also because it is one of the earliest development of optic neuritis from the ear trouble.

A case of acute purulent inflammation of the middle ear; a double optic neuritis, but without tenderness or swelling of or spontaneous pain in the mastoid process, in which the opening in the mastoid cells was followed by a rapid subsidence of the optic neuritis and cure of the ear disease.

The patient, a woman, aged thirty-five, consulted Kipp July 7, 1891. She complained of pain and throbbing in the right ear, from which she had been suffering for about six weeks. A month before the ear became affected she had influenza, which left her debilitated. The physician who attended her when she was first attacked by the ear disease punctured the membrana tympani, which gave some relief. Since then she had been syringing the ear, etc. She was not suffering much from earache then, but had a constant throbbing in the head and ears. Hearing was impaired for watch and voice. The tuning fork was better heard through bone than air, and when placed on the vertex best in the diseased ear. There was but little pus in the external canal. The walls were somewhat red and swollen. The membrana tympani was of a deep-red color, swollen, and much thickened. In its upper anterior quadrant there was a small perforation, through which air but no secretion passed during the Valsalvian experiment. The parts behind and

in front of the auricle were neither red, swollen, nor tender on pressure. Examination of the eyes with the ophthalmoscope showed them to be entirely normal. The opening in the membrana tympani was enlarged, and this was followed by syringing with warm salt solution and politizerization once a day. She improved for two weeks; then the opening in the drumhead had nearly closed, the walls of the canal were but little swollen, and throbbing in the ear was not so bad.

July 22d he enlarged the opening in drumhead, and again washed out the tympanic cavity with warm salt solution by means of a middle-ear syringe. The soft parts over the mastoid were perfectly normal, and there was no pain on pressure.

Patient was not seen again for a month. Her physician had continued the treatment advised by Kipp. On August 29th he made another examination of the ear and found it in about the same condition as at her first visit. The mastoid process was neither œdematous nor red. The ophthalmoscope revealed, however, a remarkable change in the eyes—a well-marked optic neuritis in both. Vision was not at all impaired in either eye. Her general condition had grown worse. The throbbing in head and ear was more pronounced. She felt very weak in her lower limbs, her gait was somewhat staggering, and she had occasional attacks of dizziness. She was listless and drowsy, her appetite poor; she had had neither nausea nor vomiting. Temperature, 99° F.; pulse, 72. She had had no chills nor fever.

On September 2d the mastoid was opened by Schwartze's method. After the removal of the cortex, which was about the average thickness, a cavity of about the size of a hazelnut was reached. It was filled with foul pus and granulating tissue. The cavity was thoroughly cleaned out with a sharp spoon and the mastoid antrum reached without difficulty. Free communication through the external auditory canal and mastoid wound was established. The wound was dressed in usual way. No reaction followed, and the patient then gradually improved.

A month or so after the operation there was more or less discharge through the wound, but it was never profuse. After that time it ceased entirely. A silver drainage tube was kept in the wound for three weeks, and then it was allowed to close. The otorrhœa ceased four days after the operation, and soon after the operation the perforation was found closed. The optic neuritis remained stationary for about a week after the operation, then began to subside gradually, and at the date of her discharge from the hospital, September 26th, the optic discs were almost normal in appearance.

For six months following she was seen occasionally, and when last examined she was in perfect health, having a normal drum membrane of grayish color, and in its upper anterior quadrant a scar. The opening in the mastoid was firmly closed. The ophthalmoscope showed the optic disc to be pale; otherwise it was normal. The fundus oculi was perfectly healthy in both eyes. The vision was normal.

My own case is as follows:

Patient, aged twelve, male, admitted to the New Amsterdam Eye and Ear Hospital, July 20, 1892. Otitis media purulenta, mastoid periostitis, mastoiditis interna, abscess of cerebrum, thrombosis of lateral sinus, meningitis, optic neuritis. Death.

History: The patient complained of discharge from the ear for many years. Wilde's incision was made six years previous to the patient being seen by us, by a surgeon connected with a hospital at Buda-Pest. Following the operation he had severe pain, etc., in head and ear, which in a great measure subsided but continued as a subacute condition until the time of his appearance at our clinic. His condition at that time

¹ Transactions of American Otological Society, vol. v., p. 216.

was as follows: There was a large, firm swelling over left mastoid region, which was reddened and very tender, and a slight discharge of pus from the external auditory canal. Temperature, 102.5° F.; pulse, 128. Wilde's incision was made, and three hours after operation pain was absent and temperature had dropped to 100° F.

On the evening of the day following the operation his temperature went up to 103° F., accompanied by severe pain in the ear.

On the following afternoon a mastoid operation was resorted to by method of Schwartze, accompanied by an escape of a considerable quantity of pus. By means of Volkmann's spoon about a drachm of foul-smelling caseous material was removed from the antrum, and irrigation by means of a one-half-per-cent. solution of carbolic acid was employed. During the operation a considerable surface of the dura over the lateral sinus was exposed and could be seen in the posterior part of the wound. The wound was lightly packed with gauze and absorbent dressings were applied.

As the discharge from the external auditory canal was slight, on the following day a paracentesis of the membrana tympani was resorted to. Two hours following this patient was taken with severe chills. Temperature rose to 104.5° F. The day after the temperature declined to 102.5° F., and the patient was more comfortable. The next day he had severe pain in head and eyes. Pupils contracted. Ophthalmoscopic examination revealed choked disc, left side.

For twenty days the patient continued in a precarious condition, temperature oscillating between 101.5° and 105.5° F. and pulse behaving badly. At intervals he complained of severe pain in ear and head, the latter toward the last being severe and constant in character. He was much perturbed in mind and at times maniacal.

On the thirty-first day of his entrance into the hospital patient was found to be blind in the right eye, apparently over the entire field. Ophthalmoscopic examination was *nil*.

On the following day the ophthalmoscope revealed slight venous hyperæmia on the right side and violent choked disc on the left side.

Two days later patient was afflicted with more paralysis on the right side, lapsed into a typhoid condition, became comatose, continued so for twenty-four hours, and on the forty-first day of his entrance into the hospital he died.

An autopsy was made and brought to view the following conditions: The vessels of the dura were found to be intensely engorged and lifted up. On opening the dura a layer of foul-smelling thick pus, about one-fourth inch thick, bathed the entire left hemisphere, dipping down into the longitudinal fissure and up as far as the convexity on the right hemisphere, and extending some distance over the upper parietal lobe. On lifting the frontal lobes the pia was seen to be intensely engorged. The entire base was found to be bathed in pus. The optic nerves were swollen and the sheaths distended. The cerebellum was normal; its upper portion, however, was surrounded by pus. A large encapsulated abscess was found in the anterior portion of the occipital lobe on the left side, around which the brain was softened, with considerable purulent collection, especially external to it. A cut section of brain showed the abscess cavity to be about one and one-half inches antero-posteriorly and one inch laterally. The ventricles and other portions of brain were normal. The right hemisphere was found to be normal, except for pus collections dipping down into the sulci from the longitudinal fissure.

Ear: There was extensive thrombosis of the lateral sinus, extending to the torcular Herophili. The dura was not perforated during the operation for opening

the mastoid, but at time of autopsy an opening through the temporal bone from the mastoid cells along the lateral sinus was found. The opening extended along the lateral sinus for about eight millimetres, and was about four and one-half millimetres wide. Around this the dura was adherent, and the bone at its posterior and inner border was found to be carious.

No evidence could be found of purulent infection through any of the nerve or venous canals of the petrous portion of the temporal bone. The tegmen tympani was chiselled away and the ossicles and membrana tympani were found to be absent. Communication between mastoid cells, antrum, and middle ear was found to be free.

Deductions.—From a consideration of these cases and many others in literature the following conclusions are drawn:

1. That the ophthalmoscope is of value in arriving at a diagnosis of the presence of cerebral disease—in some instances by confirming the evidence which is given by other symptoms, in others by being the principal if not the only reliable evidence of the existence of brain disease.

2. The subsidence of the optic neuritis after operation, which gives a favorable turn to the ear disease, is shown by the recovery of the eyes and their restoration to normal vision. In this connection the case of Kipp's is particularly interesting and instructive, because there were wanting positive evidences of either mastoid disease or cerebral extension until the ophthalmoscopic examination detected double optic neuritis, upon which indication alone the operation was determined upon.

3. The percentage of cases in which the lesion under consideration is found is small, as, indeed, are brain complications. Kipp thinks that in most cases where meningitis is present there is some degree of optic neuritis. This seemed to have been the consensus of opinion in the discussion which followed the reading of the paper in the American Otological Society and was participated in by a large number of members present. This may be accounted for in a large measure, I think, by the neglect to look at the eyes—an omission which I for one confess to in many of my cases. Again, the attention is frequently not directed to the eyes, because, as is well known to ophthalmologists, vision is often unimpaired even in the most pronounced inflammation of the optic nerve.

4. The intra-ocular end of the nerve is never inflamed when the disease remains limited to the middle ear and mastoid, but is a certain evidence of brain disease. If, therefore, optic neuritis is found, the diagnosis of extension to the brain is certain, no matter whether other evidence exists or not.

5. The form of optic neuritis which exists is always of the kind seen in affections of the brain, viz., choked disc; but this may vary in degree from simple venous stasis, hyperæmia of the disc, œdema of the disc and surrounding retina, to, as in my case, the most pronounced choked disc. In my opinion the various forms described are only different grades of this form of neuritis. The eye trouble and impaired vision are most marked on the side where the ear disease is.

6. The presence of optic neuritis is unfortunately no aid in a solution of the difficult dilemma of locating the situation or even the nature of the disease, although, as we shall see under another head, the latter may be inferred from its more frequent occurrence in some of these affections than in others.

7. Optic neuritis occurs more frequently in cases of otitis media purulenta chronica than in acute cases, in which, indeed, its occurrence is very rare, the case of Kipp's in this respect being the earliest example of its occurrence after the onset of the ear affection. I have found that most of those I have looked

up were observed in cases of otorrhœa of long standing, in many instances a number of years.

8. The list of brain lesions from otitis media purulenta in which optic neuritis has been observed, verified by autopsies, embraces nearly if not all those observed, *i.e.*, abscesses of brain and cerebellum, meningitis, and sinus thrombosis.

9. The occurrence of optic neuritis in a case of otitis media chronica with implication of the mastoid, with a history of long-standing otorrhœa, is by inference very apt to be due to a cerebral abscess, although it must not be lost sight of that all of the lesions enumerated may be found in the one case—as in mine, where there was an abscess, meningitis, and sinus thrombosis.

10. The extent to which the presence of slight œdema of the optic disc should influence us in determining upon an operation on the mastoid is, in the absence of other sufficient evidences, necessarily an open question. But I think we may safely accept the conclusion arrived at by Dr. Andrews, a sound one, that "as the operation when intelligently performed is not a dangerous one, without waiting for pronounced neuritis we may accept the condition of œdema of the optic disc in the case under consideration as an indication for the opening of the mastoid; and if not with the expectation of liberating pus, at least to establish free drainage from the middle ear. The procedure is certainly consistent with a good surgical principle, and is not likely to add to the pre-existing mischief." In regard to the presence of a marked neuritis alone or in connection with other symptoms being an indication to open the mastoid, no doubt can exist. Another indication of great value is pointed out by Knapp, who has been guided by the recession of the ocular symptoms in arriving at a decision when to let the opening in the mastoid (after operating) close. It is not necessary, he says, to keep up the syringing and drainage from the mastoid cavity until the suppuration has completely ceased, and it is just in these cases that the use of the ophthalmoscope has been of advantage.

11. The existence of optic neuritis as an indication for a more serious operative procedure than opening the mastoid, of the nature of an exploration of the brain for intracranial disease, can be considered only in connection with other symptoms which would go to render so grave a procedure justifiable. So far as it goes, however, it serves to make the presence of intracranial disease more certain.

A Barbarous Exhibition.—A correspondent of the *British Medical Journal* describes an exhibition of hanging which is attracting large crowds of morbid spectators in Paris: "A man is attached by a cord to the ceiling. He is dressed in a blouse, with a red muffler round his neck. His head is bent toward his chest. His face is thin and bony and appears convulsed, his eyes are almost shut, his veins are swollen, and the complexion is ashen. The arms drop down at a little distance from the body; his hands are contracted, the fingers bent. The veins are so swollen that they seem on the point of bursting. The legs hang straight and stiff. This barbarous spectacle is served up with an accompaniment of music. It is observed that when the music strikes up the hanging man is seized with painful convulsions. In this position he will remain thirteen days; after that trial he will remain buried three hundred and sixty-five, and will then take his place among the living. The rest the man takes in this hanging position consists of leaning against a ladder, which is placed in a position to permit him to doze without in the least changing his attitude. During this time he is rubbed with a sedative lotion and inhales ether. No food of any kind is taken."

BACTERIURIA.¹

By HERMANN GOLDENBURG, M.D.,

NEW YORK.

THE subject of bacteriuria, judging from the limited number of cases reported, is one quite novel in medical literature. It was first described by Roberts in 1881 and has seldom been referred to by American writers. Much of what we now know on the subject was brought out by Ultzmann in his lectures, which I had the opportunity of listening to and which were published after his death by his former assistant, Dr. Brik. In recent French literature a paper, "*Sur la Bactériurie*," has been published by Krogins, wherein he reports eight cases in which a thorough bacteriological examination had been made.

I am of the opinion, however, that the disease is more frequent than would be inferred from the scant literature on the subject and that many cases recognized as cystitis are really types of bacteriuria.

Bacteriuria is characterized, as the name implies, by bacteria in the urine. But not every case with bacteria in the urine can be classified under this term. *Sensu stricto*, the latter applies only to those cases in which the freshly voided urine contains a large number of bacteria. The urine is always cloudy, opalescent, and has a peculiarly disagreeable odor. The reaction is acid or neutral, and, if it is alkaline, there is some other cause at work. The cloudiness does not disappear on boiling nor after the addition of a mineral acid. The urine does not become clear on filtering with the ordinary filtering paper, but it does so after passing it through a Pasteur filter or by shaking it with calcined magnesia (Salkowski) or carbonate of barium (Ultzmann). When the urine is properly filtered, it does not become opalescent either on boiling or on addition of an acid, if the case is not complicated by bladder or kidney trouble. For microscopical examination a drop of aniline violet is to be added to a drop of urine on a slide, heated for a short time, allowed to cool, and afterward examined with oil immersion. Examination will then reveal an abundance of micro-organisms of different shapes and sizes, such as the ordinary bacterium termo, the bacteria of intestinal fermentation, cocci, and bacilli. In eight cases Krogins found the bacterium coli commune in pure cultures, and it seems that this bacillus is the most common cause of the disease. Formed elements are absent if the bacteriuria is not complicated by an affection of the urethra, bladder, or kidneys.

As to the symptomatology of the disease very little is to be said, as the subjective symptoms are generally absent. The peculiar odor is often the only thing that draws the attention of the patient to his ailment. The latter is in most cases exceedingly obstinate: it shows a tendency to chronicity and relapses, and sometimes no permanent cure can be obtained.

Etiology.—The bacteria being those of fermentation and identical with those found in the intestinal tract of the healthy individual, in the contaminated air, in the normal urethra, under the prepuce, on the vulva, and in the vagina, it is surprising indeed that cases of bacteriuria are not more frequently found, especially in women, in whom there is a good chance for the bacteria to enter the bladder from the vulva and vagina through the short urethra.

A question which is of the utmost importance in the etiology of the disease is: "How do the bacteria enter the urine?" The answer is, either through infection or through auto-infection.

Infection.—Ultzmann states—and his statement is copied by later authors—that bacteriuria is found in patients with malaria and in physicians who work in

¹ Read before the genito-urinary section of the New York Academy of Medicine, May 12, 1896.

dissecting-rooms, where the infection takes place through the respiratory organs. Some years ago I treated a patient with bacteriuria complicated by hæmaturia of renal origin, general malaise, and emaciation, due to malarial infection. The patient rapidly improved under quinine and salol.

More frequent are the cases in which the bacteria enter the bladder per urethram through the introduction of instruments, especially of unclean catheters.

Auto-Infection takes place from the intestines either directly through contiguity, or indirectly through absorption.

As to the direct auto-infection, perforation of a prostatic abscess either into the rectum and urethra or into the rectum alone may be the cause of bacteriuria. In the former case the bacteria are directly transported from the rectum into the posterior urethra and the bladder; if the abscess open only into the rectum, the bacteria of the intestines enter the urethra through the prostatic duct.

There is, however, another way for the intestinal bacteria, viz., through the lymphatics.

Wreden demonstrated in the laboratory of Professor Nencki that after a slight artificial traumatism in the rectum of male rabbits the bacteria coli could be found in the urine of the animals. By producing an artificial loss of epithelium in the region of the prostatic gland, or higher up, a cystitis was caused and the intestinal bacteria, as well as those which, *experimenta causa*, were introduced into the rectum, could be found in the urine. Wreden claimed that the bacteria enter the bladder directly, *per contiguitatem*, through the lymphatics which connect bladder and rectum, and was able to demonstrate that in rabbits after a superficial erosion of the rectal epithelium fatty substances, such as oil or vaseline, which were introduced into the rectum, were found in the urine.

Looking over the text-books of human anatomy I do not find a statement that in man the lymphatics of the bladder communicate with those of the rectum. Quain says: "The lymphatics of the bladder are few and small and their course and termination are not sufficiently known;" and of the lymphatics of the rectum: "Some of them pass through small glands which lie contiguous to it [*i.e.*, rectum] and finally they enter the lymphatics situated in the hollow of the sacrum."

Sappey states that the lymphatics of the bladder, although conceded by most authors, have never been demonstrated: "One sees, it is true, lymphatics on the outer surface of the bladder, but all those come from the seminal vesicles or from the prostatic gland, both of which have an abundance of lymphatics."

From these anatomical facts it seems that the infection takes place through the lymphatics of the prostatic gland or of the seminal vesicles to the peritoneal covering of the bladder and through the walls of that organ to the bladder itself.

The last mode of entrance of the bacteria into the urinary tract from the intestines is by excretion of the absorbed bacteria through the kidneys. It has been known for a long time that the kidneys are not a perfect filter, but that particles which are not dissolved in the blood, such as cinnabar, fat, etc., can pass through them.

Grawitz, Schweizer, Baumgarten, and others demonstrated that even living elements can be eliminated through the kidneys. Recently Biedl and Kraus have shown that micro-organisms which circulate in the blood can be excreted through the absolutely intact kidneys. They chloroformed dogs, fixed a sterilized cannula into the vena jugularis or femoralis, performed laparotomy on the animals, inserted cannulas into the ureters, and examined the urine thus obtained under all the necessary precautions, after having injected the staphylococcus pyogenes aureus, the bacte-

rium coli commune, and anthrax bacillus into the veins. Cultures made from the urine showed the micro-organisms which had been injected, examination of the urine was negative as to blood or albumin. They concluded that the normal kidney through its physiological function is able to excrete the micro-organisms.

Posner demonstrated the bacterium coli commune in the blood of the heart, in the kidneys, and in the urine of rabbits in which he had ligated the ureters and had caused a prolapse of the rectum and had occluded the prolapsed part with a ligature.

Treatment depends entirely on the cause of the bacteriuria. It is obvious that the therapeutics is different in cases due to an infection from without from that in cases due to an infection from within. The sceptical views of some authors as to the curability of the trouble are partly due to a too schematic therapeutic procedure. If the bacteria are introduced into the bladder through instrumentation, irrigations of the bladder and of the entire urethra with a solution of nitrate of silver, 1 to 2,000 or 1 to 1,000, are probably the most efficacious. Of internal remedies salol in doses of fifteen grains or oil of gaultheria are to be recommended. When there is a distended bladder and a disturbed contractility of this organ, the patient is to void his urine at shorter and regular intervals, as the distention of the bladder facilitates the decomposing action of the bacteria. If the bacteriuria is due to a perforated abscess of the prostatic gland and if there is no more direct communication between rectum and bladder, it is advisable to use massage to empty the prostatic gland of the bacteria which are deposited in that organ. After the massage the patient should pass his urine, and then the empty bladder and the entire urethra are to be irrigated with antiseptic solutions.

Much more difficult will be the treatment when we have to deal with bacteriuria due to an auto-infection from the intestines. Theoretically the indication is to prevent increased decomposition and fermentation *in loco nascendi* by means of intestinal antiseptics, or, if the fermentation is not abnormal, to prevent the absorption of the bacteria which under normal conditions inhabit the intestines.

The number of internal remedies recommended for intestinal antiseptics is legion and their value is inversely proportional to their number.

According to Albu intestinal antiseptics is illusory: "A great number of experimental observations have demonstrated that it is impossible to suppress the putrefactive processes in the intestines by means of internal antiseptic remedies. Nature, however, accomplishes this task by producing a diarrhœa."

Following this suggestion in the case I am about to report, I produced an artificial diarrhœa by administering laxatives, but did not find any marked effect on the bacteriuria. As this case offers some especially interesting features I may be permitted to report it at length.

The patient, thirty-three years of age, was seen by me in consultation with Dr. Manges on November 15, 1894, on account of a chronic urethritis of twelve years' standing with occasional acute exacerbations. When I saw him the profuse discharge with which he came under the doctor's care had disappeared under the usual treatment. Examination of the urine voided after irrigating the anterior urethra showed clear urine with a moderate amount of small shreds from the posterior urethra. Urine passed after massage of the seminal vesicles, which were found enlarged, of a doughy consistence, and tender to the touch, contained an abundance of pus cells, spermatozoa, detritus, and epithelia. Endoscopy showed a normal anterior urethra, a few granulations here and there in the posterior part of the canal, and hypertrophy of the colliculus seminalis.

Diagnosis: Chronic vesiculitis seminalis, mild urethritis posterior.

The treatment suggested by me and carried out by Dr. Manges, viz.: massage of the seminal vesicles, rectal cooling sound, irrigation of the urethra with nitrate-of-silver solution, caused a marked improvement, so that Dr. Manges notes on December 24th: "Urine very good, only a few shreds in first portion. The patient has had connection without any injurious effect." Treatment was discontinued, as the patient considered himself cured. He enjoyed perfect health until June, 1895, when he came again to Dr. Manges with a relapse of the same nature as before. Although while under the old treatment a marked improvement took place, a perfect cure could not be obtained. The discharge, to be sure, was very slight, but the urine, which before had been perfectly clear, became cloudy and offensive about the middle of September and remained so in spite of all treatment.

The patient, therefore, was sent to me for the second time for consultation on October 7, 1895. The diagnosis of bacteriuria which Dr. Manges had made, both clinically and microscopically, was confirmed. In order to clear up the question how and where the bacteria entered the urinary organs, a catheter was introduced into the empty bladder and the latter was irrigated with a mild boric-acid solution. On this occasion it was found that the bladder was considerably distended; the patient was able to hold an unusually large quantity of liquid without feeling a desire to urinate. The irrigation of the bladder was continued until the liquid came out perfectly clear; the catheter was then left in the bladder a sufficiently long time to receive the urine as it entered the bladder from the kidneys. This was found perfectly clear and normal, so that the renal origin of the bacteriuria could be excluded. The bladder then was filled again with boric-acid solution and in withdrawing the catheter the entire urethra was irrigated with the same liquid. The patient then passed part of the contents of the bladder and this was found clear. The seminal vesicles were then thoroughly stripped. He then passed the balance of the urine, or rather of the boric-acid solution previously injected into the bladder. This liquid was turbid and offensive, the color and odor being of the same character as the urine filled with bacteria. Microscopically, bacteria, spermatozoa, pus cells, and epithelia were found.

It thus was clearly demonstrated that the *fons et origo morbi* was situated in the seminal vesicles, wherefrom the bacteria, probably the bacterium coli commune—I regret to say that a bacteriological examination was omitted—entered the posterior urethra. It was deemed advisable to strip the seminal vesicles in order to rid them of the bacteria, which by the massage were emptied into the urethra and bladder, where they could be attacked with suitable remedies, in the form of irrigations and instillations.

For the next four weeks these suggestions were faithfully carried out by Dr. Manges, but without success. Besides massage and local treatment, applied every other day, salol, methylene blue, turpentine, oil of gaultheria, and benzoic acid were given internally. Per rectum, ichthyol suppositories were added; per urethram, AgNO₃, potassium permanganate, and ichthyol were applied, but the treatment had no effect.

In the beginning of January, 1896, Dr. Manges, to whom I am indebted for his notes of the case, kindly transferred the patient to me, but I was unable to see in what way I could be more successful in the treatment, as everything was done that I had suggested. The failure of all therapeutic procedures proved to me that the continuation of the symptomatic treatment—for such it was—was useless.

Clearly the bacteria originated in the intestines and

the indication was either to prevent their excessive formation—the patient stated that he was occasionally troubled with flatulence and constipation—or to prevent their absorption.

Close inquiry into the previous history did not reveal anything pointing to the patient having had an abscess of the seminal vesicles or of the prostatic gland. A direct communication could be excluded, from the fact that a solution of methylene blue injected into the rectum did not appear in the urine until twelve hours afterward, when it had been absorbed and excreted through the kidneys. The patient, who had watched the condition of his urine very closely, was instructed to note particularly if the bacteriuria was the same at all times of the day. His attention having been drawn to this, he noticed that when he had had an evacuation of the bowels in the early morning upon rising the urine passed between nine and twelve o'clock was fairly clear, but that it was cloudy again at subsequent urinations in the afternoon. All local and internal treatment was then discontinued, natural Carlsbad salt was ordered to be taken every morning, and the patient instructed to abstain from everything in his diet that was apt to increase the intestinal fermentation. The Carlsbad salt moved the bowels freely, but the bacteriuria remained unchanged. The patient was then advised to take enemata of soapsuds with borax, one tablespoonful of the latter to two quarts of the soap emulsion. This was carried out for one week, once daily, and at the same time the patient took enteric pills of corrosive sublimate, $\frac{1}{100}$ grain, t. i. d., purposely prepared so that they should not dissolve until reaching the intestines. While the enemata produced a free evacuation of the bowels in the morning and the urine cleared up for the first few hours after the evacuation, it was full of bacteria in the afternoon and evening. Once only, on a Sunday, when the patient could arrange to irrigate twice with soapsuds, viz., at 9 A.M. and 3 P.M., the urine was clear during the entire day, but the first urine passed the next morning was as cloudy as before.

He then consented to take two enemata regularly every day, one upon rising, the other before retiring. Under this treatment within one week the condition improved to such an extent that when he presented himself again after the lapse of the week the urine was found clear in all its portions at all times of the day. For the sake of completeness, however, I must state that for the first four days of that week the patient had taken creosote, three minims, t. i. d., in the form of enteric pills, of which twelve had been prescribed.

From my experience with the multitude of other internal medicines which the patient had been taking, I can hardly think that the cure can in any way be attributed to the twelve capsules of creosote. The enemata were continued twice daily until the beginning of March, when the patient used them only once daily until March 10th. He then discarded them entirely. The condition has not changed, the urine has remained absolutely clear and normal, and as a sufficiently long time has elapsed since all treatment was discontinued the patient can safely be considered cured.

Without any hesitation I attribute the cure to the rectal irrigations with soap and water, the excellent disinfecting properties of which have long been known and have lately been again experimentally demonstrated by Max Jolles, particularly in their relation to the bacterium coli commune.

As to the etiology of this case of bacteriuria, the clinical observation and the therapeutic result clearly point to an intestinal origin. I am inclined to believe that through the different rectal manipulations (cooling sound and massage) a superficial loss of epithelium was produced, thereby facilitating the absorp-

tion of the millions of bacteria which were in the fæces, in the glands, and in the follicles of a subject in whom the possibility was an unusually good one on account of the constipation and the increased intestinal fermentation. The infection which took place was most likely analogous to the one experimentally produced by Wreden, viz., through the lymphatics.

As stated before, there is an abundance of lymphatics going to the prostatic gland and seminal vesicles, and it is easy to understand this mode of infection.

The development of the bacteriuria was furthermore facilitated through the distention of the bladder, caused by the habit of sometimes not urinating more than twice or three times within twenty-four hours. If we consider that the normal urethra is the habitat of a great many microbes and that a thorough disinfection of the urethra is well-nigh impossible (*cf.* Petit and Wasserman), we must assume that the *vis medicatrix nature* plays an important part, inasmuch as the bladder through regular urination rids itself of the microbes introduced by instrumentation before any decomposition of the urine has taken place.

Krogus reports among his eight cases one in which a patient who had had a number of gonorrhœas developed bacteriuria, due to the bacterium coli commune. He states that in spite of all irrigations of the bladder and instillations into the posterior urethra and bladder of two-per-cent. solutions of nitrate of silver, no cure could be obtained. I believe that this case resembles rather closely in its obstinacy in the concomitant symptoms, such as increased intestinal fermentation, the one which I have just reported.

22 EAST SIXTY-THIRD STREET.

A STUDY OF HYDRAMNIOS AND SOME OF ITS COMPLICATIONS, WITH REPORT OF A CASE.

By A. P. STONER, M.D.,

CAINSVILLE, MO.

HYDRAMNIOS, or dropsy of the amnion, is an excessive accumulation of liquor amnii. It is only when the amount of liquid exceeds four pints that the term hydramnios is eligible. Its occurrence is not rare; however, the literature is not so prolific on the subject as one might be led to suppose, and I dare say that many physicians have passed their first decade in practice and not had the opportunity of studying a case at the bedside. A great deal of discussion has taken place in regard to the etiology of this anomaly, and I doubt if the cause is to be found in any one morbid condition.

On the one hand, the theory of fœtal origin has found favor with many observers, notably with Sallinger, who injected liquid into the umbilical vein and found that it transuded readily into the amniotic sac, governed as to rapidity by the amount of pressure exerted and the size of the cord. Jungbluth and Levi-son have found that a capillary network is connected with the vessels of the umbilical cord and closely interwoven beneath the amnion in that part of the chorion covering the placenta during the early part of pregnancy, but does not persist to the end in a normal case.

Between these vessels and the internal surface of the amnion there exist canalicular spaces, furnishing a number of communicating passages. Now, in cases of hepatic obstruction or of cardiac or pulmonary disease, which might clog the umbilical vessels, a transudation from this network would take place, provided it existed at the time.

On the other hand, cases have been reported in

which overproduction of the fluid was due to inflammation of the amnion itself. According to Landois, the amniotic fluid is due to fœtal origin, and is, perhaps, a transudation through the fetal membranes; and, inasmuch as it occurs in birds, this fact throws a great weight to the fœtal origin of hydramnios.

Symptoms.—The uterine distention usually begins slowly; however, a rapid increase may take place, occupying only a few days, and Sentex has reported a case occurring in a single night. The expansion soon produces discomfort in breathing, owing to the encroachment on the diaphragm. This lengthens into actual pain, by the stretching of the abdominal walls and viscera. Actual dyspnœa and palpitation of the heart occur in consequence, and the urine may become scanty and loaded with albumin. (Edema and ascites follow, a result of obstruction to the portal circulation and pelvic and abdominal vessels. Vomiting from reflex irritation takes place, and may become incessant. The patient may find locomotion difficult or even impossible.

Pregnancy rarely reaches its normal termination in cases of hydramnios. When it exists to a marked degree it produces death of the fœtus, even though pregnancy should advance to full term.

Complications.—As before mentioned, cardiac embarrassment through the pressure of the diaphragm, and nephritic obstruction from the direct pressure upon the kidneys, are produced. Should there be a tendency to organic disease in either of these organs, it is liable to become permanent; the heart is overworked, compressed, the blood vitiated from the improper oxygenation, the kidneys cease to respond to their natural duties, blood becomes dammed up, albumin passes through the filters with the other waste products, and the result is a permanent impairment. Portal circulation may suffer to a less degree. At the precipitation of labor the child may occupy any position; the occiput, breech, shoulder, or face may present: and, last but not least of the complications, may be mentioned post-partum hemorrhage.

A few cases have been reported in which congenital hydrocephalus was present, as was found in my own case. A. N. Whitam reports a case accompanied by spina bifida and enlargement of the head.

Diagnosis is usually easily made out. It may be mistaken for twin pregnancy, which is generally easily excluded by palpation, digital examination, and absence of the fœtal heart sound. Hydramnios may resemble ovarian tumor, which may be differentiated by the history of the case and the duration of the trouble, but it must not be forgotten that both disorders may be present in the same case. Ovarian tumor and pregnancy may exist at the same time, and be mistaken for hydramnios.

The Prognosis for the child is nearly always fatal; not more than twenty per cent. survive, the high mortality of the fœtus being in a great measure due to malformations and faulty presentations.

Treatment.—An abdominal binder may be worn and the patient be made to refrain from active exercise. Should grave cardiac or renal disease appear, abortion should be produced. Porak concludes that it is not desirable to rupture the membrane too early in cases of hydramnios, lest the placenta be detached and the child lost. It may also lead to post-partum hemorrhage. Lusk advises not to puncture the membrane during uterine contraction, as it would be liable to change the position of the child. Post-partum hemorrhage must be treated according to the methods laid down for the management of those accidents.

The following case, which occurred in my own practice in 1894, may be of interest: November 7th of that year I was summoned to see Mrs. A—, who was threatened with a miscarriage. She was the wife of a

farmer, fleshy and robust, thirty-five years old; had given birth to three children at full term, all of whom were now living. The youngest, two years of age, has congenital rachitis. The patient stated that she had been unable to do her housework for several weeks past, and more recently had found locomotion next to impossible; hence she had spent most of her time in bed or in an easy rocker.

Examination showed the abdomen to be enormously distended, and it was impossible to map out any part of the child by external palpation or detect the fetal heart beat by auscultation. The integument over the abdomen was sallow, glistening, and tense. Pulse irregular, respiration shallow and somewhat augmented, extremities swollen and cold. On examining the uterus per vaginam the cervix was found soft and dilatable. Passing my finger cautiously up to the sac, it was ascertained that there was a limb presenting; by gently tapping the same with the finger-tip, the child was made to bound entirely out of reach and produce a perceptible oscillation of the liquid within.

I judged from the evidence before me that I had to deal with a case of hydramnios with foot presentation. Uterine contractions were now regular and strong. The patient was bathed with soap and water, and afterward sponged with a solution of bichloride of mercury, 1 to 800, as is my custom in preparing patients for confinement. The patient was placed on a couch with clean sheets, etc. At the end of six hours, the uterus having dilated sufficiently, chloroform was cautiously administered by an assistant. The membranes were ruptured, at which time the fluid gushed out with powerful force, passing over the foot of the couch and striking the wall beyond. The flow was suddenly checked by the descent of the child. Both feet being brought down, the uterus continued to dilate regularly and rapidly, and the progress was uninterrupted until the head became engaged in the lower segment of the uterus, when it ceased to advance. Suspecting that the arms had been misplaced upward by the side of the head during the sudden descent of the child, I examined, but found them snugly folded on its breast. After cautious performance of the ordinary manipulations by traction on the body of the child, the pains being frequent and exceptionally strong, it occurred to me that there was a complication of hydrocephalus, there being no progress whatever to expulsion. Accordingly, a puncture was made in the dorsal vertebra, and an elastic catheter passed into the cranial cavity, from which about one quart of fluid was withdrawn, after which the head was readily delivered, at which time another gush of amniotic fluid poured out, thoroughly saturating the bedding and trickling through on to the floor. It was estimated that about thirty pounds of fluid were evacuated in all.

Turning my attention now to what I feared most, post-partum hemorrhage, I at once injected hypodermically one-half drachm of ergotol; but before it could have time to act, the blood began to pour forth. I quickly thrust my hands into a hot five-per-cent. creolin solution, and passed my right hand into the uterine cavity, which stimulated it to contraction; that portion of the placenta not already detached was readily loosened by a sweeping movement of my hand and forced out before it, when the hemorrhage ceased.

The head measured, when fully distended, twenty-two inches in circumference; the sutures were widely separated; the fontanelles were of large diameter; the eyes bulged and presented a hideous sight; otherwise the child was well formed and presented the appearance of a fetus at the seventh or eighth month.

The mother made a protracted but perfect recovery.

In conclusion, I would make the following suggestions:

(1) That cases of hydramnios are frequently compli-

cated with cardiac or renal disease, in which case the life of the fetus must take secondary consideration.

(2) That faulty presentations frequently accompany this anomaly and should be sought out early.

(3) That malformations of the fetus may exist and obstruct the progress to delivery.

(4) That the danger to post-partum hemorrhage is great and should be carefully guarded against.

(5) That an antiseptic management is a prerequisite to the successful treatment of these cases.

Progress of Medical Science.

Venesection in a Case of Hemorrhage into the Pons.—At a recent meeting of the Clinical Society of London, a report of which appears in *The Lancet*, Dr. F. L. Benham read the details of a case of hemorrhage into the pons Varolii in which venesection was followed by recovery. The case was that of a widow, aged fifty-three, whose mother had died from apoplexy followed by hemiplegia, at the age of fifty-five. She was a healthy woman, rather stout in build. She bore the marks of old scrofulous abscesses in the neck, but was otherwise free from organic disease. She had had two attacks of influenza in the last three years. The present illness began without any premonitory symptoms. She was suddenly seized while dressing one morning with apoplexy attended by epileptiform convulsions, chiefly on the left side, and complete unconsciousness. The eyes were shut; the head, eyeballs, and mouth were all drawn to the right side; and the pupils were much contracted, the left being rather the smaller. Respiration was much embarrassed. There was foaming at the mouth, but the tongue was not bitten. The surface of the body was pale and dusky, with a clammy sweat. Within three-quarters of an hour from the onset of the attack she was bled from the right median cephalic vein. Forty-eight ounces of blood were withdrawn. When this was done the convulsions ceased and breathing became easy; the pupils were larger and the conjugate deviation of the eyes and head was less marked. The skin was pale but less dusky. Consciousness had not returned. Five grains of calomel were administered, in addition to croton oil. There was no return of the convulsions at all; the eyes, head, and limbs moved more freely and spontaneously, but there was found to be some weakness of the right side, and later distinct anæsthesia was detected in the right arm and leg. Sensibility and consciousness gradually returned, but complete consciousness and memory did not return for twelve days, the patient describing this interval afterward as an absolute blank. There was slight aphasia during recovery. The paralysis of the left side of the face and right limbs lasted only a short time, but traces of anæsthesia in certain fingers and toes persisted for some weeks. Retention of urine occurred immediately after the apoplexy, which caused cystitis. There was obstinate constipation all along. The patient steadily recovered. In a month's time she was able to walk about the room, and in six weeks from the onset she went out of doors for a walk. She had remained in excellent health up to the time of the report, eleven months after.

Sterilization of Catgut.—Boil in a mixture of eighty-five parts of ethyl alcohol, five parts of phenic acid, and ten parts of water. Five minutes' boiling suffices for the sterilization with a temperature reaching 78° C. Without the water the process is not so complete nor so rapid.—SAUL.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, August 15, 1896.

ACUTE DISSEMINATED SCLEROSIS WITH NEURITIS IN THE SEQUENCE OF DIPHTHERIA.

THE modern toxic theories of disease processes, arising out of a knowledge of the biologic activity of micro-organisms, may be viewed as a kind of reversion to the ancient humoral pathology, with the distinction, however, that the latter-day views are based more securely upon data furnished by scientific observation, rather than upon mere inductive reasoning, however rigid. As a rule, infectious processes give rise primarily to local lesions only, the constitutional manifestations resulting from the circulation in the blood of the soluble poisons generated at the primary focus, and the secondary lesions and complications occurring through metastasis or through independent or associated secondary infections.

Diphtheria is perhaps the most demonstrative and the most convincing illustration of the foregoing remarks. Primarily a purely local process, it becomes general through the absorption of the toxic products of the reaction between the invading bacteria and the tissues, and through the activity of complicating infections, especially those due to the presence of the streptococcus pyogenes. The resulting intoxication makes itself especially manifest by the most varied symptoms, referred to the nervous system as one part or another is brought under the influence of the noxious agent. In the preponderance of cases these symptoms are referable to neuro-muscular apparatus.

The motor disabilities arising in the sequence of diphtheria vary in clinical character in accordance with the structures affected and the pathological alterations that take place. Most commonly the peripheral nerves undergo inflammation or degeneration, especially the motor nerves, although the sensory nerves do not always escape. In some instances the muscles themselves are involved in the degenerative process. In a third group of cases destructive changes take place in the ganglion cells of the anterior horns of the spinal cord. Finally cerebral hemorrhage or embolism may occur and give rise to hemiplegia of apoplectic onset.

An observation recently recorded by Henschen (*Fortschritte der Medicin*, November 14, 1896) illustrates an unusual nervous sequel of diphtheria and throws some light upon the etiology of disseminated

cerebro-spinal sclerosis. A girl, fourteen years old, previously healthy, was seized, together with a number of other persons, with an acute affection of the throat of mild type, on the second day of which she was compelled to go to bed. On the fifth day a sense of pricking and formication was referred to the lower extremities, which were tremulous and weak. On the sixth day the patient was unable to walk, and retention of urine occurred. A day later she was scarcely able to support herself on her feet. The palsy of the legs grew gradually complete, and sensibility was lost as high as the costal arch. Later the right arm became paretic and the anæsthesia extended still farther upward. The knee jerks were now increased, although subsequently abolished. The mental state remained unaltered. The cranial nerves were uninvolved, except that visual acuity was impaired on the left and the eyelids could not be readily elevated. The pupils were large and of sluggish reaction.

In the further progress of the case the left arm also became paretic; the ptosis increased; hyperæsthesia appeared in the lower portion of the face and in the right arm; the voice became nasal, the right vocal band being less active than the left; and the muscles of the throat failed in their functions. The electric irritability of the paralyzed muscles was diminished and the contractions were sluggish. The sphincter ani also became anæsthetic and a thrombus formed in the right leg. After the illness had thus continued for more than a month, improvement in the motor and sensory symptoms began to set in, but a bed sore formed, the patient wasted greatly, and broncho-pneumonia brought death. Upon post-mortem examination numerous disseminated sclerotic areas were found throughout the length of the spinal cord. These were few and small in the cervical region, where the postero-median columns had undergone degeneration. The areas of sclerosis were greater in number and extent in the dorsal region, in the lower portion of which the postero-median columns were especially affected; but elsewhere the distribution of the sclerosis was general, though smallest in the pyramidal tracts. In places the gray matter of the cord was invaded. In the affected areas the nerve fibres were more or less completely degenerated; the axis cylinders were best preserved. The separation of healthy from diseased structure was rarely defined sharply. The neuroglia of the white matter appeared increased and contained many nuclei. In the areas in the gray matter the large ganglion cells presented varying degrees of degeneration and the tissues contained numerous small glia cells, as well as fibrils. Diphtheria bacilli were looked for but not found. Degenerative changes were also present in the nerve roots. The vessels were surrounded by an abundant round-cell infiltration; the walls of the vessels, had, as a rule, undergone but little change. The nerves of the lower extremities were degenerated and those of the upper also, though in slighter degree. The brain was not examined.

While the case as reported pursued the clinical course of diphtheria, it is to be regretted that the diagnosis was not confirmed by the discovery of the bacillus of Loeffler. Accepting the diagnosis as cor-

rect, however, the observation is exceedingly interesting, as illustrating a hitherto unnoted sequel of diphtheria and as showing further that disseminated sclerosis is histologically an inflammatory process.

NIGHT TERRORS.

DR. J. A. COUTTS some time ago gave an interesting review of our present knowledge regarding the above subject, and contributes some of the results of his own experience and reflection. He says that systematic writers have not paid as much attention to this topic as its frequency and importance demand. He thinks that the descriptions given by English writers are incomplete and unsatisfactory. The American additions to the literature of the complaint, though not numerous, are of extreme value, and he refers particularly to the writings of Lyman, Wood, and Putnam. The disorder known as "night terrors" is attributable to a very wide range of causes. The list includes digestive irritation,—always the most popular one,—adenoids of the pharynx, enlarged tonsils, rheumatism, epileptic tendencies, and hysteria. Dr. Coutts thinks that there are two classes of cases, of which the common symptom is "terror" arising during sleep, and it is because of these different classes that the etiology is so variously given. In the first class there come cases of a reflex character, due to abdominal or nasal trouble. In the second class there come cases of comparative infrequency, in which the malady arises from central cerebral disturbances. For the first class of cases Dr. Coutts prefers the name of "nightmare," and would reserve that of "night terrors" for the second class only, in which the malady is of central origin. This separation has been made before, as Dr. Coutts admits, in correspondence with a classification of night terrors into symptomatic and idiopathic. The main question is, How can the physician tell when the patient is suffering from the symptomatic or idiopathic form? Dr. Coutts is of the opinion that the diagnostic points are these in true night terrors: it is essential that the patient should see visions, or, in other words, have hallucinations. In nightmare, it is sufficient that he merely dream dreams. Night terrors, he adds, seldom occur in children under the age of two or above that of eight years. In nightmare, there are no such limits of age. In night terrors there is a history of neuroses, such as epilepsy or hysteria in other members of the family, and sometimes infantile convulsions have preceded the night terrors in the history of the patient. In night terrors the attack comes on when the child is in the best of health, and is quite sudden in its onset, while children who suffer from nightmare are usually subjects of indigestion or nasal trouble, and in rather poor general health. In the course of the night there is usually but a single attack of night terrors, but there may be several of nightmare. Nightmare occurs in a child often at the end of a number of hours of restless sleep, while night terrors frequently show themselves in the form of a sudden violent explosion, so to speak. If the physician has been able to distinguish the case,

as between a serious neurosis and a dyspeptic or other reflex disturbance, the treatment is simple enough. For pavor nocturnus bromide of potassium or some similar drug is absolutely necessary, while in the nightmare of children it is necessary to regulate the diet, look after the throat and nose, and improve the general health of the patient.

THE BRITISH MEDICAL ASSOCIATION.

THE meeting of the British Medical Association in Carlisle the last week in July, a special report of which will be found elsewhere in this issue, seems to have been up to the usual average of such gatherings.

The attendance was expected to be between seven hundred and eight hundred, which is the figure usually reached at the provincial meetings, but on the afternoon of the third day only six hundred and fifty members had registered. The addresses at the general sessions were not of a very high order, and will hardly rank among the best efforts of their authors. The most suggestive was perhaps that of Sir Dyce Duckworth, on "Prognosis in Disease." The non-scientific proceedings of the last session were very stormy and the record of them was ordered to be suppressed for various reasons. The nature of the discussion can be imagined from the subject, which was "Ethics in Advertising." During the past year several men high in the councils of the association have been thought to favor, for their own use, rather unethical methods of keeping themselves before the public, while they were at the same time more or less scandalized by the employment of apparently no more reprehensible methods of obtaining the same results by their less eminent brethren. Some of these latter had an opportunity to express themselves at this meeting.

The acceptance by the association of the invitation from the Montreal branch to meet in that city next year is interesting. We believe the Canadian branch of the British Medical Association has been in existence only since 1893, and that it now feels competent to entertain the parent body next August is an evidence of healthy growth. The selection of Dr. Roddick, of Montreal, to preside at the meeting will be gratifying not only to his compatriots but to all his friends in this country as well. Doubtless many Americans will assist as spectators at the meeting in Montreal, and New Yorkers at all events will have the pleasure of meeting old acquaintances and of forming new ones among those coming to the meeting from Great Britain and Ireland. While, therefore, our Canadian brethren only have an official concern in this action of the British Medical Association, all of us, as Americans, are pleased to know that its members are coming to our side of the Atlantic.

But there is another matter of interest in connection with this move, and that is the effect it will have upon the attendance of English-speaking physicians at the Moscow congress. No one would think of attending two meetings within one month in places so remote from each other as Moscow and Montreal, if indeed the interval of time between the two conventions

would suffice for the journey. It is safe to assume, therefore, that no Canadians and but few British will go to Moscow, while the attendance of Americans would be small in any case. So doubtless the English language will be heard but rarely, notwithstanding its tardy recognition as an official tongue by the organizing committee. Whether or not the leaders of the British Medical Association intended any slight by turning their backs upon the International Congress we are unable to guess, but their action might easily bear that construction.

News of the Week.

The Heat Mortality.—The excessive heat from which we have been suffering since the 4th of this month, and from which we have only just now obtained a slight measure of relief, is almost unprecedented in the records of the weather bureau. No such long period of unbroken high temperature has been experienced, in this city at least, since 1872, even the centennial year, the miseries of which are not yet effaced from memory, having had no single term of such length of unrelenting high temperature. Fortunately, the heat was tempered part of the time by a rather low humidity. The number of deaths reported as from sunstroke in New York City alone in eight days was two hundred and eighty-eight, and doubtless these figures would be doubled were all the deaths included which could justly be attributed to the effects of the heat. The number of cases of prostration of which the police and health authorities had cognizance was over sixteen hundred and fifty in the metropolitan district. The greatest number of deaths from insolation on any one day was one hundred and twelve, the next greatest being sixty-five. The highest temperature recorded at the signal station in the city was 94° F., but this station is located some three hundred feet above the level of the streets, where the mercury ranged several degrees higher. During one of the least torrid days of the period, a thermometer placed in the sun registered 113° F.

Cholera in Egypt.—The official cholera returns from Cairo show that on August 9th and 10th there were throughout Egypt 322 deaths from cholera. Since the outbreak of the disease this year there have been 13,986 deaths.

Pennsylvania State Medical Examinations.—It is announced that of the 381 applicants recently examined for license to practise medicine in the State of Pennsylvania 340, 89.24 per cent., were successful.

Delaware County (Pa.) Medical Society.—At the regular monthly meeting of the Delaware County Medical Society, held at Elwyn on July 24th, Dr. A. A. Eshner, of Philadelphia, read a paper entitled "Some Considerations on the Treatment of Typhoid Fever;" Dr. H. W. Cattell, of the University of Pennsylvania, demonstrated Roentgen photography and exhibited a number of interesting lantern slides.

Kentucky School of Medicine.—At a recent meeting of the faculty of this school, the following lecturers were appointed: Drs. Louis Frank, clinical and operative gynecology; Henry E. Tuley, obstetrics; Carl Weidner, physiology; W. E. Grant, anatomy; Ewing Marshall, physical diagnosis; T. C. Evans, ophthalmology, otology, and laryngology.

Lehigh Valley (Pa.) Medical Association.—The sixteenth annual meeting of the Lehigh Valley Medical Association was held at Wilkesbarre on August 6th, with a large attendance. Twenty-four new members were elected, including Dr. George M. Gould, of Philadelphia, and Dr. Roswell Park, of Buffalo. Dr. Gould read by invitation a paper entitled "Some Curiosities of Medical and Surgical Practice." The following officers were elected for the ensuing year: *President*, Dr. J. R. Bucher, of Lebanon; *Vice-Presidents*, Drs. Mary Greenwalt, of Stroudsburg, G. T. Fox, of Allentown, O. F. Harvey, of Wilkesbarre, C. J. Deaver, of Reading; *Secretary*, Dr. Charles McIntire, of Easton; *Assistant Secretary*, Dr. W. S. Stewart, of Wilkesbarre; *Treasurer*, Dr. A. Stout, of Bethlehem. The executive board was constituted as follows: Drs. J. Reisser, of Berks County; A. M. Cooper, of Bucks; W. E. Seipel, of Carbon; O. H. Sproul, of Hunterdon, N. J.; J. W. Keath, of Lebanon; M. E. Hornbeck, of Lehigh; C. P. Knapp, of Luzerne; W. E. Gregory, of Monroe; J. W. Groff, of Montgomery; N. Ziegenfuss, of Northampton; Montetius, of Northumberland; and P. Hermany, of Schuylkill.

Bucks County (Pa.) Medical Society.—At the regular quarterly meeting of the Bucks County Medical Society, held at Bristol on August 5th, Dr. Edwin Rosenthal, of Philadelphia, read a paper on "Intubation for Diphtheria," exhibiting the instruments employed and demonstrating their mode of application.

Guarding against Yellow Fever and Small Pox.—Dr. Doty, health officer of the port of New York, has gone to Havana, to institute measures there for the prevention, as far as may be, of the exportation of small-pox and yellow fever on steamers coming to this city.

Dr. Bismarck.—The German universities have exhausted their supply of honorary degrees in their desire to express their appreciation of Prince Bismarck. He was already a doctor of laws, of theology, of philosophy, and of political science, and now Jena has made him a doctor of medicine. We welcome our distinguished colleague.

Physician to the Shah of Persia.—It is reported that the Shah of Persia has selected as his family physician Dr. William S. Vanneman, a graduate of the University of Pennsylvania in 1888 and formerly a resident physician in the Philadelphia Hospital.

Fees for Insurance Examinations.—One of the life-insurance companies in this city has returned to its former uniform rate of \$5 for the medical examination of an applicant, no matter what the amount of the insurance which is to be taken.

Obituary Notes.—DR. ROBERT M. BOYD died on August 6th, in Springfield, Mo., of typhoid fever. He was twenty-seven years old, and the son of the late S. H. Boyd, minister to Siam under the Harrison administration.—DR. CHARLES H. WEINHOLTZ died at his home in this city on August 7th, from the effects of some narcotic poison taken accidentally in overdose for the purpose of inducing sleep. He had been unusually busy and was suffering from insomnia. He was born in Richmond, Va., of German parents, and came to this city at an early age. He was a graduate of the University Medical College in 1883.—DR. J. A. S. GRANT BEY, of Cairo, Egypt, died suddenly on July 28th, while *en route* to attend the meeting of the British Medical Association in Carlisle.

Viewing the Internal Organs.—At the International Psychological Congress, held early this month at Munich, there was an exhibition of the "X" rays which fairly eclipsed all previous ones. The body of a man was submitted to the action of the rays through an apparatus of special design, which enabled the spectators to clearly observe the action of the diaphragm, heart, and stomach. The experiment was entirely successful.

Professor Mendel, the alienist of Berlin, was recently called to St. Petersburg to see a patient in consultation with the local physicians. Some excitement was occasioned by a rumor that it was the Tsar whom he was to examine, but this has been contradicted, although the sufferer is still supposed to be a member of the imperial family.

Suicide appears to be epidemic in Austria at present. Vienna had two hundred and seven suicides during the first six months of the year, which is double the average for the last ten years. At Lemberg, in the same period, seven soldiers in the thirtieth infantry regiment killed themselves. Quite recently a shoemaker in Vienna adopted a spectacular mode of exit. He joined a party of English tourists visiting the steeple of St. Stephen's Cathedral. When they had reached the platform from which Count Starckenberg watched the Turks during the siege of 1683, he jumped off, landing on his neck on the roof below.

Unwarranted Liberties with Medical Thought Cases.—In a certain shop in Carlisle, during the recent meeting of the British Medical Association, there was shown in the window a contrivance for taking the shape of the head when one desired a new hat. It was labelled: "Shapes of heads taken with the 'Conformateur.' Local doctors." Here followed, spread out in the window, some twelve or fifteen pieces of cord, each labelled with the name and address of the medical man whose head the cord was shaped to represent. Among those whose names and addresses were given was Dr. Barnes, Portland Square, the president of the association. *The Lancet* published quite a list of these names, innocently remarking that "of course, these gentlemen are quite ignorant of the use that is being made of their names and will take care that it is not continued."

The Health Board Sustained.—The board of health of this city has been looking into the condition of rear tenement houses and condemning all such as it deemed insanitary. An owner of one of these houses recently made application to enjoin the board from evicting his tenants, which it was doing preliminary to tearing the house down as detrimental to the public health. The petitioner did not attack the constitutionality of the law under which these rear tenements are being condemned and removed, but he denied the right of the board to order the tenants to get out before a judicial decision had been given condemning the rear tenement. Justice Stover, of the Supreme Court, denied the application, saying that under the statute the board of health is constituted the authority to pass upon the condition of the property and to determine its sanitary condition. In doing this it is performing a judicial act, and that act ought not to be interfered with by the injunction of the court, unless it should clearly appear that the board was without jurisdiction. He thought the board was acting within its rights, and although some of the features of the law appeared to be arbitrary and the proceeding summary, yet with the provision for compensation and with the rights of the property owners so well guarded, no lasting or irreparable detriment could come to the property owner. The public health demands that the provisions of the law should, in all cases in which it is once determined that they apply, be summarily and rigidly enforced. If, however, an appeal to the court is to be taken in each instance, the court becomes the arbiter of the question and the object of the statute is defeated. It was the intention of the statute to place all responsibility of the inspection and adjudication as to the condition of the premises with the board of health; and, so long as the board had facts sufficient to give jurisdiction, the court would not interfere.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending August 8, 1896: August 4th.—Passed Assistant Surgeon G. H. Barber, detached from the *New York*, ordered home, and granted two months' leave; Passed Assistant Surgeon V. C. B. Means, detached from the *Maine* and ordered to the *New York*.

Dr. James G. Kiernan has resigned the editorship of the *Medical Standard* of Chicago.

Chicago's Medical Schools.—A St. Louis contemporary says that Chicago has seventeen medical schools—nine regular, six homœopathic, one eclectic, and one "physio-medical." It must be quite a distinction there not to be a "professor."

The American Medical Association will establish its quarters permanently in Chicago, according to the count of the recent ballot of its members. Three thousand and sixty-one votes were cast out of 5,265 ballots distributed, and of this number 2,128 were for Chicago, 810 for Washington, and the rest were scattering.

Communicable Diseases in the State of Pennsylvania.—According to the annual report of the secretary of the Pennsylvania State board of health for the year 1895 recently issued, it appears that as a result of prophylactic vaccination small-pox prevailed at only nine points in the State during the year. In Philadelphia there were three hundred and ninety-six cases, with fifty-five deaths. In the town of Ashbourne the first case was mistaken for one of chicken-pox, and in the failure to adopt suitable precautions the infection spread quickly. As a result of this and a similar previous experience, a resolution was adopted by the board expressing the desirability in all cities having hospitals for contagious diseases to arrange for the practical instruction of medical students. Typhoid fever prevailed with its usual frequency. An outbreak at Oil City illustrates the resistance of the typhoid bacillus to cold and its portability in large streams for considerable distances. The disease appeared in those parts of the city that received their supply of water from the Allegheny River as soon as the ice began to melt and the material that had collected at various points along the river was washed into the stream by the melting snow—typhoid fever having prevailed during the winter in a number of towns situated higher up. There was an increased prevalence of scarlet fever, which in some places was of virulent type. Diphtheria also prevailed largely and was attended with a high mortality.

A Chance for a First-Class Thaumaturge.—It is reported in the newspapers that a wealthy and eccentric New Yorker who is blind from atrophy of the optic nerve and one of whose employees is in the same condition, has offered a fee of one million dollars to the person who will restore him his sight, the attempt to be first tried on this employee.

A Case of Double Consciousness.—There was brought into the Philadelphia Hospital on March 3d, of the present year, a man who was found on the streets and maintained that he did not know his name or the circumstances that led up to his admission or in fact have any memory of events prior to that date. In his possession was found a pawn ticket bearing the name of Brandt and by this name he was registered. After some days of observation it was found that the man presented no evidences whatever of organic disease and he was put at clerical work, which he performed with readiness and ability. He was exhibited at the meeting of the American Neurological Association in Philadelphia in June last. When a new set of resident physicians went on duty at the hospital early in July, one of their number recognized the new clerk as a former schoolmate, but the recognition was not mutual. The identity of the man was verified by a photograph in the possession of the resident physician and was subsequently confirmed by other acquaintances, as well as relatives of the patient. The man maintains that he has no definite recollection of anything that transpired prior to March 3d, although he admits that he has a vague notion of having travelled abroad. His family, who live in Kansas, knew of his

presence last in New Orleans, where he occupied a responsible position with a sugar concern. The man presents no evidence of traumatism, or of epilepsy, or of other well-defined neurosis. It has been suggested that the case may be one of malingering or of hypnotism, but it looks like an instance of double consciousness or dual personality.

The Composition of Human Fat.—Mr. C. A. Mitchell reports in the *Analyst* the results of an analysis of human fat, according to which it consists of about seventy per cent. of liquid acids, principally oleic acid, thirty per cent. of solid acids, probably palmitic, with small amounts of stearic and myristic acids, and traces of lower volatile acids.

Diphtheria of malignant type is prevalent at Mannheim, Pa. At St. Clair, near Pottsville, the disease is reported to be attaining epidemic proportions.

Ungallant Irish Students.—At the recent election of examiners at the Royal College of Surgeons in Ireland, Dr. Winifred Dickson, a fellow of the college, was selected a member of the midwifery board. There was no question as to her fitness for the place, but the students were offended and have held a meeting, and have requested Dr. Dickson to resign. The reasons are not stated, but it is understood that they object to being examined by a woman, on the plea that it is not quite proper. So great, indeed, is their modesty that they threaten, if their demand is not complied with, to transfer themselves to some other school and to another licensing body.

A Russian Dermatological Journal.—At the Congress of Russian physicians, held at Kieff during the first days of May, the members of the dermatological section voted to establish a journal devoted to diseases of the skin. The editors of the new journal are to be M. T. Stukovenkoff and O. B. Petersen.

Handsome Legacy for the University of Pennsylvania.—By the death of Dr. William D. McGowan, of Latrobe, Pa., the University of Pennsylvania becomes heir to a considerable estate, of which \$20,000 is represented by personal property, the remainder consisting of unappraised real estate.

The Effects of Alcohol.—The Women's Christian Temperance Union of Philadelphia has decided to communicate with the provost and the trustees of the University of Pennsylvania, requesting them to consider the advisability of establishing a school to be devoted, partially at least, to the study of alcoholic drinks, in connection with those of physiology and hygiene. It is suggested that a portion of the \$500,000 appropriated to the university by the legislature shall be used in establishing a school, to be known as the Rush School of Toxicology or Scientific Temperance.

The Policlinico at Rome, in which the section meetings of the International Congress were held, which was then in an unfinished state, has not even yet been completed. Professor Durante has been placed in charge of the matter, and it is now hoped that the hospital will be ready for the reception of patients in November next.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Sixty-Fourth Annual Meeting, Held at Carlisle, July 28, 29, 30, and 31, 1896.

(Special Report for the MEDICAL RECORD).

First Day—Tuesday, July 28th.

THE proceedings commenced at 9:30 A.M., by a private meeting of the council.

At 10 A.M. an extraordinary general meeting, to consider and if thought advisable to confirm a special resolution relating to medical defence, was held. This meeting was, of course, restricted to members, as it was proposed to alter the constitution of the association in order to take up the work of medical defence. The matter was fully discussed, and eventually the resolution confirming that of a recent special meeting was adopted. The association is therefore committed to an attempt to modify the "Articles." This will involve delay and an application to the High Court. Pledges were given that the matter should not be unduly hurried forward, so that the opinions of the branches could be considered. It was stated that twenty-eight branches had already approved of the proposal, and only one had expressed a contrary view.

At 11:15 A.M. there was a special service in the cathedral, with a sermon by the bishop of Carlisle, who took for his text, "Give praise to the physician, for verily the Lord created him." In the course of his remarks the bishop said: "Sickness is the dark shadow cast by sin, and it is the business and duty of the medical man to bring light to bear upon it. Medicine and religion work hand in hand, and were formerly combined in the same person, as when Christ sent his apostles to preach the gospel and heal the sick." At present, three distinguished missionary bishops of the Anglican Church began by being medical practitioners, and this was very appropriate, for the command to heal the sick involved the investigation of disease.

Chairman's Address.—At 2 P.M. the first general meeting of the association was held. DR. WARD COUSINS, president of the council, in moving the adoption of the report, mentioned the great loss that the association had sustained by the death of the president, Sir Russell Reynolds, and a telegram from Lady Reynolds was read, acknowledging the receipt of the message of condolence sent to the family by the council in the name of the association. Dr. Ward Cousins then alluded to the prosperity and increase in numbers of the association, which now consists of 16,332 members, 145 having died and 442 resigned during the year, out of a total of names on the books amounting to 15,669; during the year 1,240 new members were received, leaving a total as above. During the year the *Journal* of the association had treated a number of questions of great public importance, such as the health and physical condition of the pauper children cared for by the State, the commemoration of the Jenner centenary, and other matters. He also announced that the library and reading-room had been used by an increasing number of members, and that the former now contained eight thousand books, while thirty-five hundred duplicate copies had been presented to local medical libraries on requisition.

The subject of the registration of midwives and matters connected with the army medical service, the poor-law medical service, etc., had occupied the attention of the council; with respect to the first, Dr. Ward Cousins expressed his opinion that the delays that had taken place in bringing it forward were valu-

able, as affording the profession more time to consider the matter. He also mentioned that the number of cases of parturition necessary for a student to attend before presenting himself for examination had been increased from twelve to twenty, five of which must have been attended in conjunction with a fully qualified medical man.

The question of medical protection had given the council "days of waiting and nights of watching," for they were determined not to "rush" anything.

The president of the council congratulated himself and the association on the formation of ethical committees by almost every branch, and said that the association appeared to be waking up to a consciousness of its power and importance, and that soon the voice of the association would be that of a united profession.

After referring to the changes that had taken place in the branches during the year, Dr. Ward Cousins moved the adoption of the report, together with the financial statement appended to it.

It was moved by DR. KINGSBURY that it be referred back for consideration and further elaboration of the financial statement, which "humped things too much." He also said that Dr. Ward Cousins's speech reminded him of a missionary meeting, it was so full of encouragement and hope, for which he confessed he saw little ground. Referring to the statement that only a small number of the communications forwarded by members would be utilized, he said that anonymous articles should not be paid for; which provoked the retort that these were the only ones that were paid for in cash, for the signed articles carried their own recompense with them by giving a sort of advertisement to the writers, of which, no doubt, many made the most use they could. He did not wish to put himself in antagonism with the council, but spoke as a business man to business men.

DR. INCE seconded the amendment and wanted to know what became of the money; for no limited liability company would consent to receive a balance sheet like the one presented to them. Many fingers were dipped into the bag, and some of these fingers had long nails. He did not mean to impute impropriety to any one, but there were careful and careless cooks. The former took as much flour as she wanted out of the barrel, but the latter took so much that she let half of it fall on the floor. That was all he meant. Dr. Ince then referred to typographical errors in the *Journal*, which he did not think deserved anything like the encomiums bestowed upon it by the president. He found four typographical errors in the last number in the little word "to," and was of the opinion that two to's were too many.

DR. LAWSON TAIT supported the amendment, but only in the spirit of one who asked for information; he wanted to know why, when the council would not use more than a small percentage of the communications received, it allowed the editor to occupy two hundred and thirty columns with signed matter of his own, in addition to his unsigned editorials.

DR. LAFFAN also supported the amendment, and complained that the association had not taken any steps in the matter of pupilage. None but a few privileged teachers were permitted to take pupils. He also complained that the Dublin hospitals admitted as patients men who were well able but too mean to pay for treatment, and no notice was taken of a signed communication to that effect which he had sent to the *Journal*.

DR. G. BROWN also supported the amendment, though he approved of much that the council had done, and was of opinion that the general practitioner chiefly required to be protected against himself.

DR. RENTONE also spoke in favor of the amendment.

The amendment was then put to the meeting by the president-elect, DR. HENRY BARNES, but only thirty-three hands were held up for it. The report and financial statement were then adopted by a very large majority.

THE PRESIDENT then moved "that the best thanks of the association be given to Mr. Henry Butlin for his able services as treasurer for the past six years and for the interest he has shown in the welfare of the association." Carried unanimously.

It was then proposed that Dr. Parsons, of Dover, be appointed treasurer for three years, in succession to Mr. Butlin, and this, too, was carried unanimously in the absence of the doctor.

The meeting then proceeded to the consideration of the reports by the various committees to the council, which were duly carried without material alteration.

An elaborate report of the scientific grants committee gave rise to more discussion than the others, but presented no special features, though, *à propos* of the experiments detailed, it may be of interest to quote a passage from a sermon preached on Sunday evening, July 25th, by the Rev. James Christie, in the Presbyterian Church, Fisher Street, Carlisle, with special reference to the visit of the British Medical Association to that city. "I should never dream," said the reverend gentleman, "of lending my name as a minister of the gospel to any association mainly composed of faddists and cranks, who would seek to traverse the dogma of pure medical science or attempt to thwart any of its investigations into the causes and cure of maladies; even vivisection can be pursued with a minimum of pain and with the greatest humanity. The lower creation has been given for the use of man, and when investigation is carried out upon its living body, not needlessly or lightly, but with an earnest and reverend desire to secure the amelioration of the sad lot of so many among us, I say to the dextrous anatomist: 'Well done, brother; God give thee good speed in thy service to the human race.'"

Another Code of Ethics.—A resolution was carried inviting the council to draw up a new code of professional ethics, to be submitted to the association.

Address of Welcome.—The evening meeting opened with an address of welcome to the association by the mayor of Carlisle. He said it was his pleasing duty to tender a hearty welcome to the British Medical Association, which was the representative of the great healing profession, whose highest powers were devoted to promoting the welfare of the human race. Many societies made Carlisle their meeting-place, but this was the first time the medical association had honored the city with its presence, but he trusted it would not be the last; and in the name of the citizens he once more tendered them the most cordial welcome.

President's Address.—DR. HENRY BARNES, the president of the association, after a few preliminary remarks, observed that the question whether the Roman armies during the occupation of the district were or were not provided with medical officers was one that had not deeply engaged the attention of archaeologists; but recently during some excavations on the Roman wall a tablet had been discovered, dedicated by the first cohort to their medicus ordinarius, and the nature of the carving furnished strong evidence of the esteem and respect in which the soldiers held their physician, whose name was Anicius Ingenuus. Another point in connection with the ancient and royal city of Carlisle was that outside its walls was built the Hospital of St. Nicholas, one of the first institutions set apart in England for the reception of cases of leprosy, a disease which at that time appeared to have been a somewhat common one, and evidence had recently been discovered that King Robert Bruce was afflicted with it. It

was also interesting to note that when Edward I. was seized at Burgh-by-Sands with the attack of dysentery to which he succumbed, his physician sent for medicine to London from Carlisle, and that the apothecary's bill amounted to £134 16s. 4d., and the cost of conveying the same from London to Carlisle came to £159 11s. 10d. more. The list of drugs included distilled oil of turpentine, aromatic flowers for baths, carminative electuaries, plasters and ointments of various kinds, the oils of wheat, ash, and bay, water of the roses of Damascus, wine of pomegranates, remedies prepared from pearls, jacinths, and coral, and many more which he (the president) was unable to identify. At that time and for long afterward medicine was under a cloud, and there was but little progress to report; there was great faith in charms, witchcraft, and miraculous gifts of healing, but the services of medical men were not very highly appraised. For instance, in 1689 the bishop of Carlisle had contracted with a physician for professional attendance on himself and family for two guineas a year (much laughter, in which the bishop, then on the platform, joined, protesting apparently to Sir T. Grainger Stewart, next to whom he was sitting, that it cost him, the bishop, a good deal more than that). The plague had visited Carlisle with very disastrous results, sweeping away such multitudes that the living were scarcely able to dispose of the dead. The country at that time was in a very impoverished state, and thirty thousand families were stated to be in want of bread. Two bishops of the diocese died from the plague within a few months of each other, as did also the first wife of Sir Francis Howard, who was thought to have taken the disease from a new gown for which she had sent to London. The fact that this lady and the two bishops were each buried a few hours after their death showed the importance attached by the authorities to the speedy disposal of the victims as a means of arresting the spread of the disease. The mortality from small-pox toward the end of the last century was remarkable, when one in every seven deaths in Carlisle was due to that disease; but during the last twenty years, out of fifteen thousand six hundred and sixty-four deaths registered in the city, only four were attributed to small-pox. Carlisle has a well-vaccinated community. The president then described the services rendered to medical science by several distinguished Cambrians, making special reference to Dr. Heysham, whose tables of mortality were the foundation for the calculations of many life-assurance companies, and were known as the Carlisle tables. In conclusion, he referred to the necessity for further medical reforms which demanded their earnest consideration, and he hoped that the deliberations during the week would help forward their settlement.

A vote of thanks to Dr. Barnes for his able and interesting address was moved by SIR THOMAS GRAINGER STEWART, in a humorous and most felicitous speech, during which he touched upon the salient points of the address, particularly referring to the delicacy with which Dr. Barnes had referred to what had befallen Edward I. when that monarch was doing what no doubt he thought was his duty, but which was always a sore point with Scotchmen; while, on the other hand, Englishmen who might feel aggrieved by the reference to the Bruce could derive a crumb of comfort from the reflection that the valiant Scot was a leper.

SIR WILLOUGHBY WADE seconded, and exhorted the ladies present to profit by the sad experience of Lady Howard, and not send to London for their gowns but to buy them in Carlisle.

The motion was then put and carried by acclamation.

The Indian Medical Service.—A motion was then

brought forward by Dr. BAHADURJI, to the effect that the Indian civil medical department should be thrown open to the whole profession. Dr. Bahadurji freely admitted that at one time it was right to reserve appointments in the scientific and sanitary departments in India to the military medical officers, but he held that the time had come when a change should be made. He attended the meeting as a representative of Indian practitioners, and received a good deal of support. It was eventually agreed to refer this question to the Indian branches of the association.

THE PRESIDENT announced that twenty-two colonial delegates were expected to be present during the meeting. A branch at Pietermaritzburg was recognized. It was resolved to admit to the sectional meetings medical students resident in the district.

What is Ethics?—The ethical committee was instructed to prepare a code of ethics, to be submitted to the association. Some of the members of the council having remarked that they had never heard a definition of the term "medical ethics," Dr. D'ANSON, of Whitehaven, said he fancied they all had a notion that their ethics were comprised in their duty to their brother practitioners and their patients and the world at large, and the necessity of upholding the honor and dignity of their profession.

Second Day—Wednesday, July 29th.

THE PRESIDENT announced that Dr. Saundby had been elected president of the council for the ensuing three years in succession to Dr. Ward Cousins, to whom a vote of thanks was awarded by acclamation.

The Next Meeting in America.—It was resolved that the invitation to hold next year's meeting at Montreal be accepted, but that the business part of the meeting should be held in London and the scientific only in Canada—this because there was some doubt as to whether it would be legal to transact some of the financial and business matters outside the United Kingdom.

The Address in Medicine.—SIR DYCE DUCKWORTH then delivered the address in medicine, taking for his subject "The Prognosis of Disease." After a few modest words of self-depreciation, in which he said that the Scotch had big heads and that he was himself half a Scotsman, the speaker entered upon the discussion of his subject, one to which in spite of much progress in other directions the attention of the profession has of late years been inadequately directed. We have been too exclusively occupied in acquiring knowledge of facts and our views are thus apt to be narrowed and distorted. We are prone to argue too much from the particular and fail to see things in due proportion. The education of to-day is overladen with details and somewhat barren of the inculcation of general principles. If we are to be great in medicine we must sometimes lift our eyes from the microscope and away from the researches of the laboratories, and, rising to a higher level, survey the wider fields which lie before and beyond us. If we do so we shall come to know more of the due proportions of things relating to man as he passes through his present life. But for this we need both the talent of the ancient philosophers, who had an eye for general truth, and the qualities of the modern philosopher, whose eyes are set on particular facts. The problem now before us is to combine these in due harmony, and as he had expressed the opinion that we have somewhat failed in modern times to gather knowledge as did the ancients, he proposed to address himself to a neglected subject, that of prognosis in medicine, considered by the light of our most recent attainments. We can make advances in prognostic skill only by careful and patient study of the whole subject of semeiology, and

on few parts of our art has greater light been shed during the last half-century than on this. We cultivate the study of semeiology for three reasons: First, to enable us to make a diagnosis; secondly, to direct the treatment of the case; and, thirdly, to help us to frame a prognosis. Everything, therefore, depends on an accurate appreciation of the symptoms and the physical signs presented to us in any case. If we err at the outset, our treatment and our prognosis will also err.

There is no lack of teaching in these days directed to the subject of semeiology in its several parts; but we are apt to depend too much on our instrumental aids, and too little on a careful study of the patient, his personal peculiarities, and the intimate nature of his ailments. We thus miss the due recognition of noteworthy features proper to the whole case, features often suggesting further inquiry when appreciated by the trained eye and the open mind accustomed to consider every point in due proportion and in proper relation to the rest. The speaker was constantly training students in this direction, and imposing upon them the fact that as physicians they would exist to small purpose in the body politic and their art would be of small avail if it was not in the highest and best sense practical. The specialism so ripe among us is in danger of narrowing our conceptions of diseases.

Sir Dyce Duckworth then discussed at some length the subject of prognosis in relation to diseases generally of the several systems of the body. After that he alluded briefly to the assistance in prognosis which we may obtain from the condition of the pulse and tongue. Physicians have long been wont to gauge the degree of vital and residual power in the sick by reference to the pulse, and accurate physiological research has now made plain and placed on a scientific basis the several conditions so long known to observant physicians, thus aiding materially no less in treatment than in prognosis.

The conditions of the tongue have more recently attracted scientific attention in this direction, for a careful study of which we are indebted to Dr. Dickinson. To use his words, we may affirm that "the tongue, indeed, has a whole book of prognostics written upon its surface." The older physicians paid great attention to the condition of the tongue in diseases, and probably noted all that was observable to the eye. Modern study, however, places a different interpretation upon the nature and significance of many of the phenomena. Of the conditions which enable us to form a favorable or unfavorable prognosis, we have to take note more particularly of the dry tongue. This has always been regarded as grave. Dickinson found that patients, examined without selection, who had dry tongues of whatever origin, exhibited a mortality of fifty per cent. This indication mainly relates to prostration. "The kinds of diseases which it accompanies are chronic more than acute; if febrile, usually continued." Pyrexia and deficient secretion from the salivary and the buccal glands are the chief factors. "The tongue is found dry, glazed, and smooth in the later stages of tuberculosis, and in exhaustion from continued suppuration; dry and rough at the end of cases of cerebral disease, hepatic cirrhosis, cancer, pyæmia, and severe pneumonia." Among the conditions of the tongue which favor a satisfactory prognosis in any case are to be noted recovery of moisture, and a cleaning of fur from the tip and edges toward the dorsum.

It is not always an easy matter to certify how long a patient has to live, even in the presence of well-recognized symptoms of impending death. The end comes sometimes more rapidly and suddenly than had been anticipated. Again, life is sometimes protracted in a remarkable manner, and our forecasts are

proved to have been fallacious. Relatives and friends of the sick sometimes demand a prognosis and look to the physician to give dependable information in the most decided and dogmatic form. No part of the physician's duty demands more skill and tact than to afford a proper reply to such questions. While we must always be as hopeful and encouraging as is permissible, yet we must not shirk the unpleasant truth which has so often to be declared. The physician who brings most healing power with him to the bedside is generally one who is bright and encouraging and inspired always with good hope. The most accurate prognosis comes from him who has with care and a large chastened experience first established a correct diagnosis, and who has also learned to employ remedial measures with judgment and good sense. The younger men may often afford light in the matter of modern diagnostic methods to their seniors, but the knowledge and experience of the latter are needed, not seldom, in forecasting the issue of a case. Of this issue, the most shrewd may be perhaps the least confident, for he always remembers that no *præsentia mortis* are invariably to be relied on.

In closing he quoted the words of Hippocrates which commend to us all the study of prognosis: "It appears to me a most excellent thing for the physician to cultivate prognosis, for by foreseeing and foretelling in the presence of the sick the present, the past, and the future, and explaining the omissions which patients may have been guilty of, he will be the more readily believed to be acquainted with the circumstances of the sick, so that men will have confidence to entrust themselves to such a physician; and he will manage the case best who has foreseen what is to happen from the present state of matters."

DR. PHILIPSON, of Newcastle, proposed a vote of thanks to the orator and DR. AFFLECK, of Edinburgh, seconded the proposition, which was carried unanimously.

Third Day—Thursday, July 30th.

The Address in Surgery.—DR. RODERICK MACLAREN, of Carlisle, delivered the address in surgery, taking for his title "Preventive Surgery," by which he meant "a surgery in which treatment or operation is entered upon or undertaken for some risk or sequence which we expect to result from an existing condition, and not on account of what is actually present at the time." This he held to be a product of modern times, the outcome of recent advances in our knowledge of the intimate causes of disease, of the discovery of anæsthesia, and of the adoption of aseptic and antiseptic methods of wound treatment. Circumcision had been instanced as an example of a preventive operation, but Herbert Spencer had shown that there never was any prophylactic significance attached to the rite, but that it was originally a work of subjugation and was later exalted to a religious and tribal custom. Another old operation was the medical treatment of hernia, but it was only in recent years that it had been regarded as justifiable. The speaker then dwelt upon the conditions which render preventive operations justifiable, and said that such an operation should be devoid of risk to life both at the time and during the healing stage, and that it should not involve much suffering. Passing then to a consideration of special operations, Dr. Maclaren took up the various systems and regions of the body in succession.

The Naso-Pharynx.—This is a very important region, and one which offers a wide field for preventive surgery. Enlarged tonsils and adenoid growths produce some local discomfort, but their chief evil is that they check growth and nutrition. Children who are affected with them are generally small for their

age, anæmic, and ill-developed; but it is often striking to see the growth and development which follow the removal of large tonsils and the scraping away of adenoids. The speaker did not favor the guillotine operation, but thought it is much more satisfactory to give the patient a deep anæsthetic and cut out—or, with a blunt director, tease out—the whole structure. Adenoid growths in the naso-pharynx produce similar remote effects to those of enlarged tonsils, and the removal of tonsils is not a complete operation without a scraping away of all growths. There are few operations which accomplish so much with so little risk to the patient or trouble to the operator.

Purulent otitis is another condition calling for preventive surgery. Not every case of suppurating ears should be operated upon, for many are amenable to medical treatment, but every one, the speaker said, who has a chronic suppurative otitis media which resists treatment is in deadly peril and should be subjected to a mastoid operation—not necessarily with a view to restore hearing or even for the sole purpose of curing the local inflammation, but for the sake of averting the danger threatening the individual's life.

Cervical adenitis is often an indication of disease in the neighborhood, such as an ulcerated throat or mouth, a suppurating ear, a diseased tooth, or an eczema of the scalp, and these should be looked for and treated. If diseased glands be left alone they commonly cause years of ill-health, with the ever-present risk of the development of disease elsewhere. The operation for the removal of these glands, whether simple suppurating or tuberculous, is often difficult, owing to the deep location of the diseased bodies and their proximity to most important parts. The results following the removal of simple suppurating glands are much better than when tuberculosis is present.

The radical operation for hernia is a most important preventive surgical measure, yet it must not be too readily or rashly undertaken. So long as a hernia can be steadily kept up by a truss which does not much incommode the patient or prevent him following his occupation there is no necessity for operative interference. But if trusses fail for any reason to keep up the intestine; if the truss is painful to wear and excites repeated inflammations of the sac; or if the patient's occupation requires exceptional activity, then an operation is indicated. The operation, as now performed, the speaker believed to be almost absolutely safe, and he thought good results could be obtained from almost all the operations now in favor. Whatever secures closure of the abdominal openings brings about a cure. He described the operation for oblique inguinal hernia as the type of all. "The plan of dissecting out the sac, cutting it across at the neck, separating the peritoneum for an inch or so round the internal ring, twisting the neck into a cord, bringing it through one or other pillar of the ring by an artificial opening just large enough to let it pass, suturing it there, then stitching together the pillars of the ring behind the cord with two or three silk sutures, and closing it as thoroughly as possible, gives a result which leaves nothing to be desired. The same may be said of other herniæ, local peculiarities, however, necessitating slight modifications."

Enlarged prostate is present in one of every three men over sixty years of age, but it causes trouble in only about one in every ten of those, and even then the daily use of a catheter is often the worst that befalls the patient. But we must not wait for sepsis of the bladder before operating, and we should not defer the operation if the patient is uncleanly in his habits or if there is difficulty in passing the catheter so that bleeding is common. Suprapubic cystotomy with removal of the enlarged prostate is the operation of choice in most cases. Castration is still on trial, but

the speaker thought that the results of the operation thus far warranted a further employment.

Appendicitis next received attention. Three views of surgical duty in this disease prevail, Dr. Maclaren said. Some hold that the appendix should never be removed, that the probability of infection of the peritoneum during the operation renders the latter unjustifiable. Another opinion, held both in Great Britain and in America by men of the first authority, is that every appendix which has given rise to morbid symptoms should be removed when in a quiescent state. The third view is that only after a repeated attack of appendicitis are we justified in resorting to a preventive operation. The speaker favored the last view and brought forward the following arguments in support of it. The great majority of attacks are not repeated. Most instances of perforation are first attacks—an evidence that one seizure does not increase the probability of perforation in the case of recurrence. A milk and farinaceous diet and mild aperients are often successful in preventing return. The time for preventive operation comes after a relapse, not after a first attack. "When the operation is done during the quiescent stage, and with every possible care and precaution which human ingenuity can devise and human knowledge direct, it is devoid of risk and absolutely effective, for the source of trouble is entirely taken away."

Cancer is another disease in which there promises to be a profitable field for preventive surgery. It is probable that there is a prolonged latent period before the development of the disease at the point of inception or elsewhere. We must study carefully the earliest changes in carcinoma in order to discover the prodromic or even the first symptoms, for then we may be able to prevent it. At present the tendency is for operations for cancer to become more and more extensive, stretching out farther and farther into the apparently sound tissues, but the speaker hoped that, with greater knowledge and earlier interference, preventive surgery may come in and bring with it a small operation.

After touching briefly upon the surgery of accidents, Dr. Maclaren concluded with a few words on the prevention of surgical diseases, referring especially to the necessity of looking after the plumbing of our modern houses, but above all to the care of the teeth. He had known death from septicæmia or putrid thrombosis originating in a dead tooth root, and he suspected, as the result of many examinations of the teeth in cases of gastric ulcer, that the latter might occur by direct infection by food or saliva containing septic micro-organisms derived from carious teeth.

A vote of thanks was passed to Dr. Maclaren for his excellent address.

The Gold Medal of the Association was presented at the close of the address on surgery to Surgeon Captain Harry Frederick Whitchurch, V.C., I.M.S. The president of the association, Dr. BARNES, having briefly related the circumstances which took place during the Chitral expedition that led the association to select Surgeon Captain Whitchurch to be the recipient of what he (the president) described as the "blue riband" of the profession, then hung it round the gallant officer's neck, amid loud applause from the large number of people assembled, one lady in the gallery getting so excited that her hat fell off into the arena below.

The subsequent proceedings of the general meeting related to business and other matters regarding the association and the action of some of its officials. Some of these proceedings were of such a decidedly stormy character that it was voted that they must be regarded as private.

The President of the Association.—DR. T. G.

RODDICK, of Montreal, was duly appointed president-elect for the meeting in that city in 1897. Great satisfaction was felt at the decision to visit the Dominion and it was decided to hold the meeting at the end of August, immediately following that of the Association for the Advancement of Science, to be held also in Canada, thus affording British practitioners the opportunity of attending both within the holiday period.

SECTION ON MEDICINE.

First Day—Wednesday, July 29th.

Address of the Chairman.—DR. GEORGE F. DUFFEY, of Dublin, delivered the opening address, taking for his title "Some Historical Notes." He said that he had the honor to be the first Irishman to preside over a meeting of this section, except on three of the four times that the association had met in the sister island. The first meeting held in Ireland was the thirty-fifth, in 1867, under the presidency of the distinguished physician and teacher, William Stokes. It was the same year that Mr. Ernest Hart assumed editorial charge of the *Journal* of the association, an office which he has held ever since, except for a brief interval in 1869-70. At the time of this meeting there were three thousand and eighty-two members on the books of the association. The date of the second meeting in Dublin was 1887.

Set discussions were first held at the thirty-fourth annual meeting, in Leamington in 1865. They were then held in the general meetings, the first subject, the discussion of which was opened by Dr. (now Sir) B. W. Richardson, being on the question, "Is there any Foundation for the Hypothesis of the Origination of Disease by Zymosis or Ferment?" At the forty-sixth meeting, in Manchester in 1877, the discussion of special subjects was transferred to the section meetings. He hoped that in the important discussions which were appointed for the present meeting of the section of medicine the members might realize with Trophilus (as recorded in the Greek inscription on a wall in the medical department of the Oxford Museum) that the perfect physician is he "who is able to distinguish between what can and what cannot be done."

Treatment of Heart Failure.—SIR THOMAS GRAINGER STEWART then opened the discussion on this subject. If there was to be no other result, he said, the comparing of notes would be valuable; but there would be more, as no doubt would appear in the course of the discussion. The muscular fibres of the heart unable to discharge their functions are greatly benefited by rest, which alone often brings about a cure. As a rule, however, private patients do not derive so much benefit from this mode of treatment as do hospital patients, who are generally working men and women whose condition is mainly due to overwork, and they unquestionably are greatly improved by complete rest, which they cannot get in their own homes. At one time the mere suggestion that the patient had disease of the heart was tantamount to signing his death warrant; but all that is altered now, and many forms of heart disease can be not only alleviated but cured by treatment.

Private patients, as a rule, derive more benefit from diet. Highly nitrogenized food must be either denied or supplied in greatly reduced quantity, and the amount of liquid taken into the system is to be materially reduced; the drier the diet, the better. Many cases of fatal cardiac failure are undoubtedly due to the ingestion of large quantities of fluid at a meal.

Alcohol taken in moderation—that is to say, not more than four ounces during the twenty-four hours—

has a beneficial effect in the class of cases under consideration.

Exercise, either passive, as massage, or according to the Schott method of treatment, is frequently of the greatest benefit.

It is possible to determine accurately the area of cardiac dulness by percussion, but the new photography will shortly render such manipulations unnecessary (the speaker presented two photographs of large size taken recently, that showed the heart quite distinctly, as well as the buttons of the man's clothes); the heart area is reduced by passive exercise, when an improvement is also manifested in the cardiac sounds and the rhythm of the pulse. Cases in which the Schott exercise certainly did harm improved when massage was substituted for it. Other cases were improved not by massage but by active exercise: a happy medium must be observed, and the nervous influence must not be overlooked nor the element of hope, both of which are factors in the successful issue of whatever mode of treatment is adopted. Another method is that by baths containing salines and carbonic-acid gas, but this gives the best results when combined with exercise, active or passive, as the case may indicate.

The old remedial medicines are by no means to be laid aside, and in digitalis we have the most powerful cardiac tonic known, though strophanthus runs it close and occasionally can be given when digitalis is not tolerated. The latter acts by inducing contraction of the muscular fibres and diminishing the flow of blood: good results have followed the use of caffeine and theobromine. The speaker advised caution in the use of diuretics, but thought that iodide of potassium was of use only in cases in which inflammation or some syphilitic complication coexisted with the cardiac disease; when such existed its effect was often remarkable, while in others it seemed to exert no influence whatever.

Tapping the pleura when there was even but a very little effusion was productive of benefit, but tapping the abdomen was to be deprecated, and the speaker had recourse to that expedient only after everything else had been tried. Opium when judiciously administered was invaluable, and sulphonal, chlorodyne, and Hoffman's anodyne were extremely useful, too.

To sum up, the speaker proceeded to say that the remedial agents in cases of cardiac weakness were rest, diet, medicinal agents, and Schott's treatment; but he doubted the necessity and often the desirability of sending patients a long and tedious journey to Norway, when the same treatment could be obtained nearer home.

DR. HERRINGHAM stated that his experience led him to give the preference to digital over auscultatory percussion for determining the area of cardiac dulness; the latter was available over soft parts, but over bone it was absolutely of no use whatever.

DR. CALDER LEITH doubted whether percussion could be relied upon in the living subject, and believed that it was the carbonic acid contained in the bath and not the salines that acted upon the heart of the patient subjected to that mode of treatment. He also thought that the patient breathed an air charged with the gas, which acted directly on the blood-vessels. Not only must the element of hope be taken into account in such cases, but the patient's mental and individual peculiarities were factors that should not be overlooked.

DR. EDMONT found that the effects of the Harrogate baths largely charged with saline matters and taken at a temperature of from 92° to 96° F. were but transient, but the position of the patient during the bath was important. On the whole, he preferred the bath to exercise, whether passive or active, and had

found the pulse to drop from 150 to 65 in the bath in a case that was aggravated by movement, but which recovered when recourse to the bath was again had. Children are often terrified by the bath, and in this case he, as a rule, prefers movement. He has it in contemplation to give the needle bath a trial, and thinks the good effect produced may be the result of reflex action.

DR. LIDDELL concurred with Sir Thomas G. Stewart in a general way. In one case that came under his notice the pulse dropped suddenly from 125 to 74, when the patient said he felt better than he had for months. He, the speaker, agreed that the element of hope played a most important part in these cases, and asked how long the treatment was to continue. One of his patients was able after three months to resume work, and experienced no return of his ailment. More experience was wanted.

DR. SAUNDEY considered that the essential points of the treatment were the temperature of the bath and the amount of saline matters contained in it. Digitalis caused recession of the apex of the heart before the Schott treatment was heard or thought of. He deprecated using the different modes of treatment concurrently, and thought with other speakers that hope was a potent factor in all these cases.

DR. BYROM BRAMWELL preferred the old to the new plan of treatment, but admitted that the latter may come in usefully at times and in certain cases. The sheet anchors, however, are rest and cardiac tonics, and he could endorse every word said by the opener of the discussion in this connection. To his medical brethren he would say: "What would you like to be done if you were the patient?" No doubt there were many supposed cases of cardiac failure that had benefited immensely by a visit to Norway, and the virtues of the treatment pursued there were loudly proclaimed, especially by neurotic women, who had enjoyed their holiday and labored under no cardiac complication whatever. Muscular movements assist the circulation, and photography was about introducing to us absolute certainty in the diagnosis. No drugs are more useful than digitalis and strychnine, especially when combined with perfect rest and rectal feeding. Great benefit had resulted in his experience from the mode of treatment he laid down, for much cardiac disorder was the result of a distended stomach and congested liver.

DR. A. MORISON thought there were cases of cardiac shrinkage that were not open to doubt, but he held them to be of rare occurrence. He thought they resulted from stimulation of the peripheral nerves, and was of opinion that the Schott treatment was more useful in cases of mitral than of aortic disease.

DR. BEZLEY THORNE thought rest was a fundamental part of the treatment when exercise was not applicable, but in other cases it did harm. Massage was valuable and so were drugs, neither of which were excluded by the Schott method. He did not agree with the undue limitation of fluid, but, on the contrary, gave water freely; not much with the meals, but when the process of digestion was about complete he allowed a large quantity of water to be taken, and found it advantageous. A limited amount of water conduced to the storage of toxin in the blood, and free diuresis cleared it all away.

DR. JAMIESON believed in the Schott treatment. He had just returned from Norway, and was of opinion that the method there pursued was an admirable adjunct to other methods, but in cases of aneurism and dilatation of the blood-vessels it was not so useful as some of the older plans of treatment. He instanced a number of cases in support of his contention.

DR. BARR remarked that the uniform peripheral pressure in an ordinary bath amounted to one-fourth pound

to the square inch of the surface of the body, and that would have a tendency to raise the arterial tension. The bath was therefore inadvisable in cases of mitral stenosis, to which the tension was prejudicial. He thought good was accomplished by the limitation of ingested fluid, but suggested that the diet should be so regulated as not to produce toxin in the system, and then there would be no necessity for washing it away. He utterly disagreed with the idea of rectal feeding; it was never intended that man should take his food that way. Formerly we gave enemata of egg and brandy—the latter was absorbed, the former was left; now we give peptonized matters, and free toxin is actually formed in the rectum, taken up by the rectal veins, and carried into the circulation.

DR. RUSSELL thought there was a tendency on the part of the public to want to be sent to Norway, but the treatment practised there could be carried on nearer home. He thought it possible accurately to determine the outline of the heart during life.

DR. KINGSCOTE thought it was possible correctly to determine the outline of the heart during life, but not by the ordinary methods. He, however, had devised an instrument for the purpose, which he showed, and for which he also claimed the advantage of being able to outline the kidneys from behind. It was most important that the part percussed should not be made to vibrate, and his instrument obviated this. A sheep's heart slung in a square cardboard box could be accurately outlined by means of his instrument, which could be obtained from Down Brothers, Borough, S. E. He had treated about three hundred cases by the Schott method, including some of fatty and gouty heart, as well as some due to various internal congestions, but the method was of less use in instances in which there was valvular disease, and in which a relapse might be looked for in about six months.

DR. HARRY CAMPBELL thought that a widespread muscular contraction stimulated the heart, and baths were useful by causing involuntary contractions, but he attached no importance to the constituents of the bath.

DR. EARLE had found that a bath the temperature of which was 75° F. caused the pulse to fall rapidly, and he accounted for the phenomenon on the theory of the rapid abstraction of heat from the body. Carbonic acid in the water prevented the sensation of cold, which at once became noticeable if the little sheet of bubbles was brushed off from any part of the body.

DR. FISHER had found that cases of hypertrophy benefit more than those of valvular disease of the heart, especially those of hypertrophy due to a toxic agent, such as alcohol.

SIR THOMAS GRAINGER STEWART, in closing the discussion, said that he was not going to make a speech, for they were all beginning to be more or less conscious of cardiac failure and anxious for an adjournment to give them an opportunity for treatment by the stomach. He would merely remark that carbonic-acid gas combined with salines had, in his experience, afforded the best results.

Chorea and Rheumatism.—DR. T. CHURTON, of Leeds, then read a paper on the "Rheumatic Causation of Chorea," and remarked that it might follow arthritis but not a chill, unless there was cerebral excitement coexisting; while sudden emotion might be followed by instantaneous collapse and death—instancing a case of a young woman who was suffering from chorea, and who, on being found to be pregnant, though every care was taken not to let her know that her condition had been discovered, instantly fell down and died in a few minutes.

DR. SAMUEL HYDE presented a paper advocating "The Treatment of Sciatica by Means of Baths and Climate;" DR. A. G. BARRS, of Leeds, one on "Alcoholic Cardiac Failure;" DR. WILLIAM RUSSELL, of

Edinburgh, one on "Abdominal Cases Illustrating Diagnosis;" DR. HARRY CAMPBELL, of London, on "Respiratory Exercises in the Treatment of Disease;" DR. JAMES CAGNEY, on "Early Energetic Treatment of Infantile Paralysis;" DR. G. V. PEREZ, of Teneriffe, on "New Auscultatory Sign in Mediastinal Affections;" and DR. HERBERT SNOW, of London, on "Opium-Cocaine Treatment of Carcinoma (with Cases)."

AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION.

Fifty-Second Annual Meeting, Held in Boston, May 26, 27, 28, 29, 1896.

THE PRESIDENT announced the presence of Acting-Governor Walcott, of Massachusetts, who addressed the meeting briefly.

President's Address.—DR. RICHARD DEWEY then delivered his address, entitled "Our Association and Our Associates," in which he represented psychiatry not as one science, but as the outcome of many sciences which were as its handmaids. He treated of the relations of alienists to the general medical profession, to the trustees of hospitals, to a properly constituted controlling State board having visitory and advisory powers, but no right to paralyze the independent energies of superintendents or trustees.

The Neuron Theory.—DR. THEO. W. FISCHER, in a paper on "The Neuron Theory and Cerebral Localization," held that the brain cortex should be divided into excitable and non-excitable areas—the former to be subdivided into sensory motor centres for all the different muscular movements. The non-excitable cortex posterior to the excitable area may be subdivided into centres of special sensation. The remainder will constitute the area of general tactile and muscular sensibility. The neuron excitable cortex in front of the ascending frontal convolution relates to mental operations and conscious voluntary movements.

Word Deafness.—DR. W. L. WORCESTER then gave the history of fourteen cases of "Paraphasia and Word Deafness," which had been under his care, and in several of which autopsical examination showed embolism and softening of brain tissues about the island of Reil, and involving also the first temporal convolution on the left side. These cases, he said, often got into hospitals for the insane, and as the dementia was sometimes more apparent than real it became a nice question in these instances as to whether they were proper subjects.

Gynecology in the Asylum.—DR. R. M. BUCKE read a paper with this title, in which he held that as a part of the physical examination women on admission should receive gynecological attention, and, if found locally diseased, should be treated as they would be in general practice if sane and likewise affected with uterine troubles. Out of thirty-four women who underwent gynecological operations in his asylum fourteen recovered their reason promptly and some of them most unexpectedly, seven were improved by the operations, eight derived no benefit, and five died subsequently.

Thyroid Treatment of Catalepsy.—DR. J. G. ROGERS reported the results in "Some Cases of Catalepsy under Thyroid Treatment." He mentioned the cardiac and other disagreeable features attending the administration of the remedy, which he deemed powerful for good or evil, and to be accepted in psychiatry as a most valuable addition to our materia medica, judging from the decided improvement in the

mental condition of some of his patients, but to be employed with cautious discrimination.

Psychic Influence of the Night.—DR. A. B. RICHARDSON read a paper on the "Psychic Influence of the Night Season," showing the general loosening of mental inhibition and the predominance of fear and other depressing emotions at night, both in sane and insane persons.

DR. JOHN B. CHAPIN, of Philadelphia, then brought out some important forensic points in a paper on "Several Writs of Habeas Corpus and What Became of Them." He mentioned among other things of interest that the judges of courts in Pennsylvania, since 1896, in dealing with insane persons seeking release through habeas corpus proceedings, based their decisions not so much on technicalities of law as on the higher ground of the medical welfare of the patients, remanding them to the hospital for further treatment, if it appeared for their best interest, without regard to the question whether they were dangerous to others in the legal sense of the term.

Neuritis in the Insane.—DR. E. N. BRUSH read an excellent clinical analysis of the symptoms of "Four Cases of Insanity Associated with Peripheral Neuritis," which had been under his personal care.

State Care of the Insane.—DR. CARLOS F. MACDONALD then made a lengthy special plea for State maintenance of the dependent insane in New York, as finally established with such great success by the commission in lunacy guided solely by humanitarian views, rising above political influence and personal motives, promoting harmony among officials of hospitals and largely extending their powers, and seeking with paternal solicitude naught but the welfare of the unfortunate patients.

There being neither assent nor dissent to the paper, a New York superintendent arose to apologize for such ideas of their own as he and his associates had held, as everything was now merged in harmony under the controlling commission.

Disorders of the Muscular System in Insanity.—DR. THEO. H. KELLOGG, of New York City, then read a paper with this title (see p. 217).

Deformities of the Hard Palate.—DR. WALTER CHANNING, in a paper on "The Hard Palate in Idiots," based on a comparative study of several hundred casts made by himself and selected from large numbers of school children and idiots, concluded that definite generalizations could not yet be made on this subject, and that too much importance had been attached to palatal deviations as stigmata.

General Paralysis in Sisters.—DR. AUGUST HOCH, of McLean Hospital, presented a report of "General Paralysis in Two Sisters," aged eleven and sixteen years, with report of an autopsy on one, and gave a detailed account of the microscopic lesions of the cerebral cortex, basal ganglia, and spinal cord, he having found extensive lesions of fibres and cells in all these regions.

The association then adjourned, to meet in Baltimore next year.

Practical Use of the Microscope.—Dr. Ohlmachee (*New York Medical Journal*) comments on the fact that a large majority of physicians in the United States possess microscopes and are unable to employ them satisfactorily even in their routine daily work. This fact is due to a lack of familiarity with methods of microscopic laboratory work. This is a reflection on the educational methods practised in medical college laboratories, especially since many young and enthusiastic men are markedly deficient in this respect.

Clinical Department.

A CASE OF POST-MORTEM CÆSAREAN SECTION, WITH DELIVERY OF A LIVING CHILD.

By HENRY S. STEARNS, M.D.,

NEW YORK,

VISITING GYNECOLOGIST TO THE CITY HOSPITAL.

PERHAPS the conditions most commonly calling for a post-mortem Cæsarean section are the sudden death of the mother from traumatism, hemorrhage, or eclampsia. And in such cases the delivery of a living child is certainly the exception. This is my reason for reporting the following case:

Mrs. S—, aged twenty-eight years, a primipara, menstruated last on July 4, 1895. Up to the beginning of January pregnancy advanced in quite a normal manner, save for a very intractable morning nausea and vomiting. In November a troublesome cough appeared, but there were no physical signs of any consolidation nor were any tubercle bacilli found in the sputum.

Early in January the cough became more persistent, with considerable pain in the larynx when swallowing. Physical examination revealed many coarse and fine mucous râles scattered over the chest, with a small area of consolidation at the right apex. Tubercle bacilli were now very numerous in the sputum. About the last of January small round gray nodules, probably tuberculous, could be distinctly seen on the epiglottis, with considerable œdematous swelling of the tissues around the vocal cords. Dysphagia became extreme, no local treatment having anything more than a very temporary beneficial effect. This, combined with the persistent vomiting and hectic, caused rapid emaciation. In February it was determined that the most advisable course was to induce labor at once, but the procedure was not consented to by the family of the patient. From this time she gradually sank, her temperature ranging between 99.5° and 102.5° F. Urine became more and more scanty, the daily average during the last two weeks of her life being eleven ounces, but containing no albumin.

Labor began on the morning of March 27th, and in the evening, when I saw her for the first time that day, the pains were very weak and absolutely ineffectual. Pulse, 160; temperature, 101° F., and unconscious about half of the time. By midnight, absolutely no advance having been made, and as any effectual interference would have certainly resulted in her immediate death, it was determined to wait for the patient's decease naturally, and then, if possible, save the child through an abdominal incision.

At 3:15 A.M. she was sinking rapidly, and all preparations were made for the section. Death occurred fifteen minutes later, and as soon as the family could be persuaded to leave the room, the incision was made and a living female infant delivered. The time elapsing between the death of the mother and delivery of the child can, of course, only be approximately stated, but was certainly not more than five minutes.

When delivered the child was deeply cyanosed, but began to breathe in a minute or two in response to the usual stimuli.

An interesting point was the action of the fetal heart, it remaining perfectly steady up to within two or three minutes of the mother's death, but after that it could not be detected even with the stethoscope.

At birth the infant weighed four and one-half pounds, when one month old five pounds, and at the time of writing—May 25th—she weighs a trifle over six pounds. During the first three weeks she was fed

on a diluted and peptonized milk: but, having considerably more digestive disturbance than seemed necessary for even such a puny specimen, a change was made then to "modified milk" from the "Walker-Gordon Laboratory." This change resulted favorably on its general condition, all gastric disturbance ceasing very promptly and appetite increasing materially.

21 EAST FORTY-FOURTH STREET.

INDUCED ABORTION, PERFORATION OF THE UTERUS, WITHOUT PERITONITIS.

BY ORISSA W. GOULD, M.D.,

NELLORE, INDIA.

DECEMBER 2d, 10 A.M., a Sudra woman, aged about thirty-six, who had walked fifteen miles, came to the dispensary, exhibiting what at first sight appeared like a superficial abdominal abscess.

History: Twenty days previous criminal abortion was induced, and since that time the patient had suffered severely with pain and had had attacks of fever, and for several days a very foul discharge.

Examination: Fluctuation over a place the size of a dollar, surrounded by deep induration, the whole being five inches in diameter. Two fingers' breadth below the umbilicus a hard point was felt just beneath the integument.

Bimanually: The body of the uterus reached nearly to the umbilicus, but was not fully outlined, because of the abscess. The anterior lip of the cervix was enlarged and resistant. Pressure made over the abdomen on the hard point felt beneath the integument was conducted to the finger on the anterior lip. Nothing was felt in the os. There was a foul purulent discharge. The temperature was normal, the pulse strong and regular.

Not being prepared for operative interference then, I gave an antiseptic douche, inserted an iodoform tampon, and put the patient to bed.

3:30 P.M.—Temperature, 101.4° F. The woman had suffered much pain since entering; her bowels had moved twice. The hard point on the abdomen had disappeared, and projecting from the os was a stick the size of a large knitting-needle. This was removed without difficulty. It measured eight inches in length.

December 3d, A.M.—Temperature normal, pulse good. There was a foul sanguino-purulent discharge from the opening in the abdomen, like the discharge from the cervix, which was increased by pressure on the abdomen. Slow intra-uterine irrigation, 1 to 50 carbolic, with hips elevated, was ordered.

1 P.M.—Chill, followed by temperature of 103° F. The internal os was at once dilated, and I removed a foul strip of cloth six inches long, irrigated again, and ordered quinine and stimulants.

6 P.M.—Temperature, 100.2° F.; pulse good. Another irrigation.

December 4th, A.M.—Temperature normal. The body of the uterus was much reduced in size, but there was still some discharge from both cervix and abdominal wall. I made a small incision in the latter and put in a short drainage tube. Intra-uterine douches were continued for two days, when all discharge had ceased.

December 8th.—The patient was discharged. The abscess was closed and the uterus was reduced to its proper size.

This case was interesting in many points, viz., the perforation of the uterus, the presence of the stick in it for so many days, the abdominal abscess evidently induced by irritation, the speedy and complete recovery without peritonitis or septicæmia

REPORT OF A CASE OF SYMPHYSEOTOMY.

By FORBES R. MCCREERY, M.D.,

NEW YORK.

THE recent revival of the operation of symphyseotomy has aroused such widespread interest that the following case seems worthy of report:

Mrs. R—, aged thirty, IVpara. In her first labor the child was lost, after a very difficult forceps operation. In her second I attended her. There was a marked projection of the promontory of the sacrum, with a resulting internal conjugate of only three and one-fourth inches. After a tedious labor, I applied forceps above the brim and delivered with great difficulty. The infant lived only three-quarters of an hour. When she was pregnant for the third time, I decided to bring on labor at the middle of the ninth month. This was, however, unnecessary, as the membranes ruptured two weeks or more before term. Two days later I again applied forceps above the brim, and delivered with moderate difficulty. The child was small, but thrived and is still living.

Her fourth labor began with rupture of the membranes on October 19, 1895. Pains began on the 21st, and continued strong and frequent till the afternoon of the 22d. The os was then one-half dilated. The head was still above the brim. The patient was becoming exhausted and begging for relief. She was then seen in consultation by Dr. John A. McCreery, who agreed with me in my proposition to divide the symphysis. The patient was accordingly etherized and the operation begun. I made the usual incision above the pubes, passed my finger down behind the symphysis until I felt the subpubic ligament, and divided it and the other ligaments by cutting from below and behind upward and forward with a blunt-pointed bistoury. The urethra was held to one side by a staff. Very free hemorrhage followed the incisions, but was controlled by pressure. The bones separated about two inches. The child was then delivered without difficulty by forceps. It was asphyxiated, but ultimately revived and is still living.

The after-treatment was troublesome. I sutured the upper part of the wound, introducing iodoform gauze into the lower angle, applied wet bichloride dressing, and strapped the hips. Two days later I removed the drain. A considerable amount of fluid blood followed. The drain was reinserted superficially. The following day it was again removed, and as the wound was apparently healing, there being no discharge, I sealed it with iodoform gauze and collodion, and put on a dry dressing. On the fifth day the temperature rose to 101° F., and the right labium was œdematous. On removing the collodion a large amount of bloody pus welled up from the wound. The probe entered two and one-half inches. I then inserted a drainage tube, and irrigated twice daily with bichloride solution. The wound soon began to granulate, and the temperature fell to normal. On the ninth day I removed the strapping and found that it had caused an ulcer to form over the right ilium. This was covered with boric acid and sterilized gauze, and the hips were restrapped. From that time on the case progressed favorably. I kept her in bed four weeks. The sinus closed in about five weeks. A fortnight later it reopened to a depth of one inch, but soon closed. Seven weeks after the operation there was a separation of about one-half inch at the symphysis, with slight motion. She walked well. I have not examined her since, but have frequently seen her and cannot observe the slightest abnormality in her gait. She says that she has no difficulty whatever in walking.

CONSTIPATION AFTER CHILDBIRTH, PRODUCING SYMPTOMS OF PUERPERAL INFECTION.

BY R. P. MYERS, M.D.,

HONOLULU, H. I.

I DELIVERED Mrs. —, primipara, aged twenty-eight, on January 1st. It was a natural labor, save that it was tedious. On the third day the temperature rose to $102\frac{1}{2}^{\circ}$, fourth day $104\frac{1}{2}^{\circ}$. Upon inquiry I found she had an operation from the bowels daily before delivery, also daily after the birth of the infant. The lochial discharge was very scanty—scarcely any, and none after third day. There had not been the slightest hemorrhage during delivery, only a few blood stains. It was truly a dry labor. I used warm carbolized vaginal douches with no result. I then ordered copious warm injections per rectum, followed by a large dose of salts. This resulted in an enormous discharge from the bowels. The temperature fell at once to normal and remained so until the woman got up well, on the twelfth day after delivery.

TWO CASES OF AN ENLARGED ASCENDING PHARYNGEAL ARTERY, SITUATED ON THE POSTERIOR WALL OF THE PHARYNX.

BY E. HARRISON GRIFFIN, M.D.,

NEW YORK,

LECTURER ON DISEASES OF THE THROAT AND NOSE AT BELLEVUE HOSPITAL MEDICAL COLLEGE; ATTENDING SURGEON FOR THE THROAT AND NOSE, OUTDOOR DEPARTMENT OF BELLEVUE HOSPITAL.

VERY few of these cases are on record. The two that I report are the only cases that have come under my observation during my throat experience of fourteen years at the Bellevue Hospital throat clinic.

Dr. J. W. Farlow, of Boston, reported five cases in the *Boston Medical and Surgical Journal* of March 31, 1887. Mr. Sanderson reported a case in the *British Medical Journal* of September 1, 1887, and Mr. Crisswell Baber in the same journal of March 1, 1887.

The fact that the pharyngeal artery may in some cases be as large as the radial artery in the wrist and at the same time lie superficially on the pharynx, so that its pulsations can be plainly seen and counted, gives an importance to a rigid examination of the pharynx before such an operation as excision of the tonsils or even an opening of an ordinary quinsy, as an injury to this vessel when so situated and enlarged would mean a copious hemorrhage and anxiety to the operator, which could have been avoided if the pharynx had been thoroughly inspected and the point borne in mind that in some cases the pharyngeal artery receives the dignity of being one of the large medium arteries of the body.

CASE I.—A woman, aged forty-nine, came under my observation one year ago, complaining of difficulty in swallowing. An examination of the throat showed the hard and soft palate covered with about a dozen cicatrices, stellate in form and having that peculiar appearance that diagnoses a past syphilitic infection. A small cicatrix was also situated on the pharynx, showing a past ulcer now healed.

The large number of these trademarks showed that at some remote period her throat had been covered very extensively with superficial and deep ulcers of a syphilitic nature.

The history of the case was as follows: The patient had married at eighteen years of age, and had had a number of miscarriages and dead-born children. Pains in the tibia bones and repeated headaches were present.

From her history, I would place the primary inoculation at about her first year of marriage. When she applied for treatment at my hands, in conjunction

with the numerous cicatrices, a large pulsating tumor was visible, situated on the right side of the pharynx, extending from its extreme end to almost its median line, in size about the volume of a lead pencil. It extended downward on the pharynx to the distance of an inch and one-half. It gave her no trouble whatsoever. The difficulty in swallowing was due to an acute attack of follicular tonsillitis. The tenderness in her throat subsided after the tonsillitis was cured.

CASE II.—A woman, age forty-five, German, applied for treatment for a nasal catarrh. An examination of her pharynx showed a large pulsating vessel on the left side of the pharynx about a quarter of an inch inside the posterior pillar of the fauces.

The artery was about the size of the one I have reported above, namely, as large as a lead pencil. It extended above the margin of the soft palate and as far down as I could see by depressing the tongue with the spatula. This abnormal condition of the artery gave rise to no symptoms.

It is an interesting fact that all the cases of an enlarged ascending pharyngeal artery reported, occurred in females and not one, so far, has been reported in a male subject. Out of the five cases Farlow reported, the artery was on both sides in two cases.

112 WEST FORTY-FIFTH STREET.

AN EMERGENCY—OBSTETRICAL AND EPIS-TOLARY (INVERSIO UTERI).

BY H. S. KILBOURNE, M.D.,

FT. CLARK, TEX.

SURGEON U. S. ARMY.

IN the vicinity of this frontier station is a camp of Seminole negroes, once residents of the opposite side of the Rio Grande, whither they had fled soon after the removal from Florida to the Indian Territory of the Indians who held them in slavery. Of late years they have been drifting back toward their native soil. The public schools of this State are open to their children. Their familiarity with the country along the border has led to the employment of some of them as scouts in the military service, in which some of them have gained distinction. Their language is a curious *patois* of Spanish, English, and the Seminole dialect, in various degrees of admixture. Early one morning recently the following note was handed me by a breathless negro boy:

"Dr please come down here my wife had a birth to a kidd this moing an hir woum all come out please come an see if you come

"CHIAKLE DINNEL

"BROTHER JOHN DENNIL"

I lost no time in responding to so moving an appeal. On reaching the cabin I found a young colored woman, primipara, who just before daylight, without assistance of any kind, after a quick labor of one and one-half hours, had delivered herself of the "kidd" lying beside her. "Hir woum all come out" I found extended between the thighs. The inversion was not quite complete and hemorrhage had ceased. The prolapsed organ was replaced without an anæsthetic and without much difficulty. It went back to its place with something of a snap, like the return of a dislocated humerus to its socket. The child and placenta had been shot out, I was told, with similar suddenness.

"Chiarle" had been sent on a mission to a ministering neighbor and I left the patient in her hands, without pain or threatening symptom. In the evening "Brother John dennil" rode in with the following note:

"Doctor yo told me if the thing was most all right she had her causes right after i left. Do yo think

that she will need that sereange and she left with a gripem like a, rinning off at the blatter"

I judged that "the thing was most all right" and sent the necessary instructions in regard to the use of the "sereange." Her "causes" have continued to progress favorably and the "gripem" was no worse than is common. The recovery promises to be complete.

REPORT OF THREE CASES OF PHTHISIS PULMONALIS FOLLOWING SCALD OF THE CHEST.

By J. N. HALL, M.D.,

DENVER, COL.,

PROFESSOR OF THERAPEUTICS AND CLINICAL MEDICINE, UNIVERSITY OF COLORADO.

IN the past three years I have treated three cases of pulmonary consumption in which the trouble originated upon that side of the chest which had in infancy been severely scalded, as evidenced in each case by an extensive cicatrix. In each instance there was contraction of the side of the chest upon which the scar was found. It seems reasonable to suppose that this contraction, by interfering with the normal lung movements, may have at least determined the development of the disease upon this side of the chest, and possibly when, without this element of danger, the patient might have successfully resisted the exposure to tuberculosis.

CASE I.—A. B.—, twenty-four years of age, printer, single, a dispensary patient. He had worked in a Chicago printing-office, but in the spring of 1893, developing cough and loss of weight, he consulted a physician, who told him that he had consumption and advised a change of residence to Colorado. I treated him during the summer and fall of that year, and reported his case in the December number of the *Colorado Climatologist* of 1894 as one of arrested phthisis, not mentioning the fact that he had marked contraction of the right chest as a result of a scald in infancy. I did not at that time fully realize the possible connection with his chest disease. When I first saw him he presented dulness, bronchial respiration, and abundant fine râles over the right chest above the fourth rib, front and back. By December he had regained eighteen pounds of his lost weight, thus bringing it up to the normal, while cough and all other symptoms had disappeared. The dulness and bronchial respiration, of course, remained in his right chest. He insisted on returning to Chicago, but came back in three months, worse off than when first seen. He was gradually regaining the lost ground when I lost sight of him.

CASE II.—L. G.—, American, machinist, single, from New York. His mother's brother died of phthisis and a younger brother has now some serious chest disease, apparently of the same nature. When two years of age the patient was severely scalded over the left chest, an extensive cicatrix and some contraction of the side remaining. He states that he had a pleurisy eighteen months ago, but apparently, from his story, without effusion. During the past few months he has fallen in weight from one hundred and fifty pounds to one hundred and thirty-two, and has developed cough, night sweats, expectoration, and dyspnoea upon exertion. He has marked dulness and bronchophony in the upper half of the left chest, and abundant moist râles in the region of the second rib. Similar signs, but much less marked, are found over the remainder of the left lung, and respiration is much diminished. The heart is displaced one inch and a half to the left, and its area of dulness increased by the retraction of the left lung. The patient has resided upon a ranch here for the past five months, and, al-

though he has gained sixteen pounds, still coughs considerably and has nearly as much expectoration as upon arrival. The only change in the chest signs consists in a lessened abundance of the moist râles.

CASE III.—S. T.—, forty-one years of age, dentist, married, American, recently from Connecticut. He states that his family was considered scrofulous, but there have been no cases of consumption to his knowledge. He nearly lost his life when two years of age from a scald of the right chest, caused by his pulling a vessel of hot water over on to himself. A large and markedly roughened and contracted cicatrix remains over the second, third, and fourth ribs, with moderate contraction of the chest upon this side. He has been failing for three or four years, and has complained for some two years of cough, expectoration, dyspnoea, loss of weight, and debility, not materially benefited by his residence for the past eleven months in Colorado. There are dulness, bronchophony, and abundant moist râles above the fourth rib, front and back, upon the right side, and very slight dulness with a few moist râles over the left chest near the sternal end of the clavicle. There seems to be no reason to doubt that the trouble originated upon the side where it is now so extensive. His urine has a specific gravity of 1.024, one-fifth by volume of albumin by the heat test, and abundant granular and fatty casts and fatty epithelial cells. He is gradually failing.

The report of these cases must enforce, I believe, the fact, long recognized, that it is the lung which is prevented from expanding to the fullest extent which offers a harbor to the bacillus tuberculosis. It is imperative, in my opinion, in the treatment of scalds of the chest involving contraction, if we would avoid the grave danger of phthisis, to adopt the same precautions as regards diet, exercise, residence, occupation, and all other factors entering into the etiology of phthisis, that we now do in the treatment of other conditions involving limitation of expansion of the lung. In view of the long interval in each case between the receipt of the scald and the development of the disease, it seems scarcely possible that any other factor than the contraction, so markedly developed after injuries of this nature, could have been operative.

CONGENITAL ABSENCE OF THE UTERUS, FALLOPIAN TUBES, AND OVARIES.

By W. HARPUR SLOAN, M.D.,

PHILADELPHIA, PA.

C. D.—, aged twenty-four, died after a protracted illness, which was of such a complicated nature that a diagnosis was not arrived at, although the most prominent symptoms pointed very strongly to peritonitis with marked cerebral involvement.

The patient was small of stature, of the brunette type, well nourished, and fleshy. Her appetite was always voracious. She was subject to periods of unconsciousness, that would last from ten to twenty minutes at a time, and after being revived from one of these attacks she appeared exceedingly bright, and was invariably hungry and would eat a hearty meal with a ravenous appetite.

Her family history was good, mother and father both living and well. She had one brother, who enjoyed good health. The patient herself had none of the usual diseases of childhood. She was blind from birth, although her other faculties were good. She had never menstruated in her life.

Post-mortem: Externally the body presented nothing worthy of note, except a poorly developed condition of the breasts, with an entire absence of the nipples; the areola was well marked on each breast. The mons veneris was totally devoid of hair.

The brain was congested, especially the right lobe, with marked meningeal engorgement: the dura mater was also much congested.

The right lung was in a normal condition; the left one much congested.

The heart was normal, except that it was slightly displaced to the right.

The stomach was dilated and contained food partly digested.

The liver was markedly hyperæmic, containing large masses of a cheesy substance throughout, while the capsule of Glisson was drawn extremely tight over the whole organ.

The spleen was normal, as were also the kidneys and bladder, the latter containing a large quantity of acid urine.

The most interesting find was that there was an entire absence of the uterus, Fallopian tubes, and ovaries, there being no evidence of their existence even in an immature state. The vagina had a normal external opening; the clitoris and labia majora and minora were normal, as were also the meatus urinarius, vestibule, and hymen. The vagina ended in a cul-de-sac with no farther extension or development.

CYCLOPIA.

By F. H. ALLEN, M.D.,
STAPLES, MINN.

THE mother of the monster here described is a Finlander, who has always enjoyed good health and has had three other healthy children. The "freak" was a girl baby, born at seven months. She weighed at birth five pounds eight ounces, and was well developed

with the exception of the face. Here the nasal bone seemed to be wanting, while the orbits were fused together, making one large, four-cornered, staring eye about the centre of the face, with a fleshy teat over it, probably representing the soft parts which should have gone to form the nose. The child lived for about half an hour after birth.

To Preserve Rubber Instruments.—It has been recommended (*Zeitschrift f. Krankenpf.*, April, 1896) that rubber instruments be kept in a three-per-cent. solution of carbolic acid. Should they not be used frequently they should be removed and stretched occasionally.

Therapeutic Hints.

Pulmonary Tuberculosis.—

R Potassii iodidi gr. xiv.
Iodi pur. gr. xv.
Sodii chloridi ʒ iss.
Aquæ dest. O ij.

M. S. Take three or four tablespoonfuls in a glass of milk three to six times daily.

—RENZI, *Jour. de Méd. de Bordeaux*.

Tinea Favosa.—Dr. Khrenitchek (*Semaine Médicale*, 1896, No. 8) recommends washing the scalp with tincture of green soap and shaving the affected area. Then the following mixture should be applied. If the hair grows rapidly the shaving may be repeated every two or three days.

R Acidi carbolici,
Balsami peruviani āā ʒ iiss.
Petrolei,
Glycerini āā ʒ iij.
M.

Local Anæsthesia.—

R Chloroform 10 parts.
Ether 15 "
Menthol 1 part.

The anæsthesia resulting from this application lasts about five minutes.—LE GERANT and E. PIERRE.

Acute Coryza.—

R Zinci phosphidi gr. viiss.
Extracti belladonnæ gr. vi.
M. fiant pilule No. xl. S. One twice edaily, after each meal.

In case of general impairment of nutrition one grain of arsenious acid may be added to the foregoing prescription.—*Gaz. Hebdom. de Méd. et de Chir.*, No. 42.

Dry Eczema with Pruritus.—

R Menthol gr. xxx.
Resorcin gr. xv.
Sulph. precip ʒ iiss.
Zinci oxidi ʒ iiss.

Tinc. chlorof. comp ʒ v.
Aquæ camphoræ ad ʒ i.
M. S. To be taken when breathing is difficult.

—*The Practitioner*.

Sick Headache.—

R Sparteine sulphate 0.02 gm. ($\frac{1}{3}$ gr.)
Caffeine 0.1 gm. ($\frac{1}{2}$ gr.)
Antipyrin 0.5 gm. ($\frac{7}{2}$ gr.)

Taken at intervals of two hours until four have been taken, even though the pain has disappeared.

—ARITZMAN, *Presse Médicale*.

Strangulated Hernia.—After several days of futile efforts at reduction the patient was placed upon the back with the hips raised and the legs flexed. At intervals of ten minutes two teaspoonfuls of sulphuric ether were poured over the tumor and strangulated parts. The surrounding skin was protected by vaseline. Slight efforts at reduction were made at first; the tumor gradually diminished beneath the hand on making gentle pressure and at the end of half an hour had completely disappeared.—FRIEDLANDER, *Wiener med. Woch.*

Salol in Vaseline, its best solvent, is found by Dr. Colombini (*Riforma Medica*) to possess a local action in contact with alkaline fluids or living tissues which is far superior to that of the salicylic acid and phenol into which it is decomposed, the usual irritant properties of these substances being lost. The skin and inflamed surfaces are found not to be irritated and ulcerations heal without pain or local reaction.

Prostatics may be benefited, Dr. Bazy thinks (*Presse Médicale*, February 29, 1896), by thyroid medication. He asks if there is not some relationship between the thyroid body and the prostate. The effects observed by him would lead him to believe that a study of the question in old men might have good results.

Neuralgias.—

R Menthol,
Guaiacol.....āā 1 gm.
Alcohol abs.....18 "
M. S. Apply one drachm locally two or three times in twenty-four hours and cover with cotton.

—SABBATANI.

Thyroidin is the name by which Wermerhen has designated an amorphous substance which he believes to be the active principle of the thyroid gland and which he extracts from it in the following manner. The thyroid pulp is left for twenty-four hours in contact with twice its weight of glycerin. This is pressed and filtered through absorbent cotton. Absolute alcohol is added to the filtered liquid, which precipitates the thyroidin.

Thyroproteid is a substance extracted from the glands by Notkine, who believes it to be the determining cause of myxedema by accumulating in the blood. The true product of the gland he thinks is a soluble ferment which neutralizes the thyroproteid, transforming it into thyroidin. This neutralization takes place in the circulation.—YVON, *Arch. de Neurol.*, March, 1896.

Poisoning by trional in daily dose of one and a half grains for a period of thirty-six days has been reported by Hecker. The patient showed extreme intellectual and physical signs of paralytic dementia. Suppression of the drug caused the alarming symptoms to disappear.—*Arch. de Neurol.*, November 3, 1896.

Syphilitic Neuritis of the secondary period, probably due to an embryonal infiltration of connective tissue and leading to destruction of nerve fibres, is benefited by the daily injection of a cubic centimetre of the following solution:

R Benzoate of mercury..... 0.25 cgm.
Pure chloride of sodium,
Chlorhydrate of cocaine.....āā 0.06 cgm.
Distilled water.....30 gm.
—CHAMPENIER.

Syphilis of the Cord.—In this infrequent affection most active measures are requisite. Vesication the whole length of the vertebral column, followed by a dressing of mercurial ointment, has produced most marked improvement.—MAURIAC.

Iodides Other than That of Potassium, in the Treatment of Syphilis.—Dr. Brizuet draws the following conclusions: 1. All the iodides have anti-syphilitic properties. 2. Iodide of potassium is usually the most active; iodide of rubidium, often better tolerated, seems to be almost its equal. 3. When iodide of potassium is not well borne there need be no hesitation in having recourse to iodide of sodium, which often acts well. 4. Iodide of strontium has no advantage over others. 5. Iodide of ammonium should be reserved for certain cases of grave syphilis

if the potassium salt disagrees or is not active; it seems especially useful in tertiary eruptions. 6. Iodides of lithium and calcium act more slowly and less surely than those mentioned. 7. To secure an effect equal or at least comparable to that which iodide of potassium gives, all other iodides must be prescribed in the same doses.—*Journal des Mal. Cut. et Syph.*, p. 87, February, 1896.

Vomiting in Pregnancy.—

Acetanilid.—Dr. Wimble (*Pittsburg Medical Review*, May, 1896) says he concurs with what Dr. Morton, professor of surgery in the Philadelphia Polyclinic, has said, namely: "I have employed acetanilid locally in a large number of surgical affections, with results so surprising in some respects as to make it difficult to restrain enthusiasm in commenting upon the antiseptic properties of the drug."

Konig-Maas Method of Resuscitation from Apparent Death by Chloroform.—Dr. Ludham-Green (*Birmingham Medical Review*) says the efficacy of this method lies in its direct action on the heart. It restores both respiration and circulation. If, on a fresh cadaver, the precordium be quickly and forcibly compressed, a distinct impulse wave in the carotid arteries is easily detected, and the pupils will contract as the blood fills the capillaries of the iris. The authors direct that the operator should stand on the left side of the patient and face him, placing the ball of the thumb of the open right hand upon the patient's chest at a point between the apex beat and the sternum. The thoracic wall should then be repeatedly pressed in with quick, strong movements, at the rate of from thirty to one hundred and twenty times per minute.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

A WEEK OF CONGRESSES—LIVERPOOL, GLASGOW, CARLISLE—PHARMACEUTICAL CONFERENCE—PUBLIC HEALTH AND SMOKE PREVENTION—DEFECTIVE SIGHT OF SCHOOL CHILDREN—INQUIRY INTO OPHTHALMIA—WATER FAMINE.

LONDON, July 31, 1896.

THE season of congresses is upon us—some irreverently call it the “silly season.” Three meetings concurrently should satisfy the appetite for this form of entertainment. It is a rather “far cry” to Glasgow, and to include Liverpool and Carlisle *en route* is too fatiguing a preparation for letter writing. You have your own reporters at Carlisle, so I may give the go-by to the proceedings of the British Medical Association and refer your readers to the reports of the several sections which you print. The same day that this began—Tuesday—the Pharmaceutical Conference opened at Liverpool, when Mr. Martindale, the author of the “Extra Pharmacopœia,” delivered the presidential address. He passed in review many of the changes he has witnessed in his quarter of a century’s experience. The new medicaments introduced in that period are numerous and of the highest importance. It was natural for so eminent a pharmaceutical chemist to dwell upon them. Many of the older drugs are now produced by much improved processes in a purer condition and yet at a lower price. On all these points and many others Mr. Martindale discoursed out of the fulness of his knowledge in a pleasant enough manner. When he came, however, to condemn in indignant phrases the Royal College of Physicians for leaving pharmacology out of the subjects for a separate examination, I thought he was going beyond his province and was only echoing the discontent of the protesting professors of pharmacology. To pretend that those who have not passed a separate examination in pharmacology will be unable to prescribe any but the simplest remedies is manifestly absurd, and I wonder Mr. Martindale should venture on such a prediction. Were men afraid to prescribe before the recent effort to alter the meaning of the word pharmacology? Are they not now injecting organic fluids, about which even Mr. Martindale himself knows but little? He was more at home in advocating the metric weights and measures, which are to be introduced into the new pharmacopœia as an alternative to the old system.

At Glasgow the Public Health Congress has had a discussion on the smoke nuisance, and the following resolution was passed: “That as the information put before this congress shows that the undue emission of smoke from the chimneys of mills, factories, and hotels can be prevented by careful firing or mechanical stokers, and without causing extra expenditure to the owners, it is desirable that the local authorities should enforce the smoke-prevention clauses in their local acts or in the general acts more stringently than they have hitherto done.” A gentleman from London gave the metropolis an excellent character in this respect; even went so far as to say that though there were five millions of people in London, they would not have smoke. From furnaces, perhaps, but however much clearer the air in London may be than that in Glasgow, I could not admit it to be comparable with many smaller cities. The gentleman from London felt, no doubt, the depression of the still murkier Glasgow.

Mr. Brudenell Carter has made a report to the education department on the eyesight of school children in London. He finds only 39.15 per cent. possess

normal vision. Slight hypermetropia is the most common defect, but is seldom sufficient to require glasses. Myopia is not frequent and is less both in number and degree among girls, who have sewing as well as lessons to do, than among boys. Hence, Mr. Carter concludes it does not depend on defective lighting of the rooms or other school cause. He was struck by the large proportion of subnormal vision, and suggests as a cause that town children have not the opportunity of cultivating the sight by looking at distant prospects. The eyes of eighty-one hundred and twenty-five children were examined for the purpose of this report.

A more important question respecting the eyes of school children is the prevalence of ophthalmia, and the local government board has entrusted an inquiry on this subject to Dr. Sydney Stephenson, who possesses special qualifications for this task. He will have authority to inquire into the condition of every child in London chargeable to the poor law. This will be a laborious undertaking, involving inspection of some twenty thousand children, but Dr. Stephenson has already had great experience in ophthalmia and is just the man for the work.

The water famine in parts of London is exciting considerable fear as to its effects on the public health.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 8, 1896:

	Cases.	Deaths.
Tuberculosis.....	144	79
Typhoid fever.....	27	9
Scarlet fever.....	41	4
Cerebro-spinal meningitis.....	1	1
Measles.....	92	8
Diphtheria.....	149	21
Small-pox.....	0	0

Treatment of Stytes.—The following treatment is suggested for this troublesome condition: Locally, as soon as the evidence of a styte is appearing, an attempt may be made to abort it by cauterizing the spot with the fine point of a galvano- or thermo-cautery. In other instances, if it cannot be aborted it is best to aid the maturation of the boil by providing warmth and moisture, and evacuating the pus as soon as this is formed. In order to render the eyelid perfectly aseptic, it is well to wash the margins of the lid with one of the following solutions, hot:

R Bichloride of mercury..... grs. iv.
Distilled water..... O i.

Or in place of this, if it is thought the individual will be susceptible to the action of the mercury:

R Bichloride of mercury..... grs. ij.
Distilled water..... O i.

In other instances an ointment made as follows is of value:

R Powdered calomel..... grs. iv.
Vaseline..... “ lxxx.

As a general rule, stytes tend to return, owing to auto-inoculation. Care, therefore, should be taken that the edges of the lids are kept well cleansed, and if necessary a mild antiseptic wash should be used for some time after one styte has healed, in order to prevent the coming of others. Careful attention should also be

paid to the condition of the alimentary canal, and it is pointed out that Bouchard believes that auto-intoxication from the alimentary canal may result in the formation of styes, through the entrance of staphylococci into the sebaceous glands of the lids. Very often in these cases the administration of naphthol is of value for this reason. The following prescription may be employed:

R Benzo-naphthol..... $\frac{1}{2}$ i.
Ft. in capsul. No. xxx. One to two capsules three times a day.

Or if the patient is young, with scrofulous, arthritic, or anæmic tendencies. Fowler's solution in full doses may be administered with great advantage.—*Therapeutic Gazette*, June 15, 1896.

Preparation of Gauze Dressing.—Dr. Martenson gives the following directions: Rolls of cheesecloth about thirty yards in length are folded and placed in jars. On these the following solutions are poured, depending upon what kind of gauze it is desired to produce. Carbolyzed gauze, five-per-cent.:

R Colophene 50 parts.
Castor oil 15 "
Carbolic acid..... 25 "
Alcohol, 90 207 "

Three hundred parts by weight of this mixture are taken to five hundred parts of gauze. Or the following may be used:

R Vaseline 30 parts.
Carbolic acid..... 25 "
Benzin..... 242 "

Three hundred for five hundred of gauze. Thymolated gauze:

R Thymol..... 10 parts.
Essence of turpentine 3 "
Paraffin oil..... 10 "
Benzin..... 200 "

Three hundred and three of the solution to five hundred of the gauze. Sublimated gauze:

R Bichloride of mercury..... $1\frac{1}{2}$ parts.
Chloride of sodium $\frac{1}{2}$ part.
Glycerin..... 15 parts.
Distilled water..... 500 "

Equal parts of the solution and gauze are employed. Iodoform gauze:

R Iodoform..... 50 parts.
Paraffin oil..... 10 "
Ether..... 400 "

The weight ratio between the amount of solution used and the gauze is four hundred and sixty to five hundred. The gauze is allowed to soak for twelve hours in this solution, is then dried, and stored in an antiseptic, air-tight jar.—*La Médecine Moderne*.

Intra-Uterine Photography.—Dr. Pinard has reported an experiment performed by Varnier and Chapuis on the uterus of a woman who died of pernicious anæmia in December, 1894, at which time she was three and a half months pregnant. This is reported as the first intra-uterine use of the Roentgen rays (*The University Magazine*). The specimen had been frozen and divided by two sagittal cuts and preserved in spirit. The surfaces were accurately adjusted and secured by rubber bands. The cavity of the uterus appeared clear in the centre of the photograph; the outline of the specimen was distinct, and the inequalities in the thickness of the muscular wall could in part be

detected. The picture was crossed by two light vertical lines, the lines of the section and two dark horizontal bars portraying the rubber rings. The fœtus could be seen lying at the upper and right side of the cavity face downward, and extending from the fundus to within about four cubic centimetres of the lowest part of the inferior segment. The head was flexed on the thorax and completely in profile, but the ribs and spinal column, which finished very black, showed that the trunk lay obliquely to the right and backward. The outline of the neck, occiput, vertex, and forehead was well marked; that of the nose, mouth, and chin not so distinct. Near the elbow of one of the arms flexed with the hand on the forehead, two dark parallel bands indicated the radius and ulna, and the lower part of one thigh with the knee and lower leg and the dark shadow of the femur were quite evident. Both walls of the gravid uterus, the bladder, placenta, rectum, and fatty tissue had proved more permeable to the rays than the rubber bands a half millimetre in thickness. In the photograph the fœtus and its position were more distinctly seen than through the unbroken membranes of an aborted ovum. Pinard believes that it is probable that the uterine wall will be as easily traversed by the rays when recent and full of blood as when hardened in alcohol, and that the position and attitude of the fœtus can be thus ascertained in post-mortem specimens without freezing, and so interfering with their microscopical examination.

The Old World's Centenarians.—A German statistician has studied the census returns of Europe to learn a few things about the centenarians of the Old World. He has found, for instance, that high civilization does not favor the greatest length of life. The German empire, with 55,000,000 population, has but 78 subjects who are more than 100 years old. France, with fewer than 40,000,000, has 213 persons who have passed their 100th birthday. England has 146, Ireland, 578; Scotland, 46; Denmark, 2; Belgium, 5; Sweden, 10; and Norway, with 2,000,000 inhabitants, 23. Switzerland does not boast a single centenarian, but Spain, with about 18,000,000 population, has 410. The most amazing figures found by the German statistician came from that troublesome and turbulent region known as the Balkan Peninsula. Servia has 575 persons who are more than 100 years old; Roumania, 1,084; and Bulgaria, 3,883. In other words, Bulgaria has a centenarian to every thousand inhabitants, and thus holds the international record for old inhabitants. In 1892 alone there died in Bulgaria 350 persons of more than 100. In the Balkan Peninsula, moreover, a person is not regarded on the verge of the grave the moment he becomes a centenarian. For instance, in Servia, there were in 1890 some 290 persons between 106 and 115 years, 123 between 115 and 125, and 18 between 125 and 135. Three were between 135 and 140. Who is the oldest person in the world? The German statistician does not credit the recent story about a Russian 160 years old. Russia has no census, he says, and except in cases of special official investigation the figures of ages in Russia must be mistrusted. The oldest man in the world is then, in his opinion, Bruno Cotrim, a negro born in Africa and now a resident in Rio Janeiro. Cotrim is 150 years old. Next to him probably comes a retired Moscow cabman, named Kustrim, who is in his 140th year. The statistician says the oldest woman in the world is 130 years old, but neglects to give her name or address, possibly out of courtesy, or perhaps in view of the extraordinary figures which came to his hand from the Balkans he thought a subject only 130 years old was hardly worthy of particular mention.—*Medical Review*.

APPENDICITIS AS IT AFFECTS LIFE INSURANCE RISKS.¹

By ALBERT WOODS, M.D.

WORCESTER, MASS.,

MEDICAL DIRECTOR OF THE STATE MUTUAL LIFE INSURANCE COMPANY.

No disease has assumed more importance in recent years, or excited greater interest in the medical profession, both at home and abroad, than appendicitis. It has been studied by the ablest physicians and surgeons in this country and in Europe, and their contributions have followed each other in rapid succession, so that now its literature has become voluminous.

From such abundant material, one would think that the necessary data could be easily collected to show the relation which this disease bears to life insurance; but I have studied many of the scholarly articles upon this subject, published within the last ten years, and I have failed to find just the information needed to enable me to form an intelligent conclusion.

Wells published in the *Medical Examiner*, in November, 1894, a valuable paper on "Appendicitis and Insurance" that contained many important facts, a knowledge of which is necessary to appreciate fully the bearing of this disease upon insurance. Besides this, I have found scattered through the medical journals only one or two short items in which any allusion has been made to this disorder, from an insurance standpoint.

To obtain exact information, I addressed a letter of inquiry to the various companies, to learn the practice of each in dealing with an application of a person giving a history of appendicitis. The replies showed such a remarkable difference in the methods of the several companies in deciding upon this class of risks that I was strongly impressed with the importance of bringing this subject before this association for discussion, and with the necessity of our trying to formulate some uniform rules for the guidance of all the companies.

In this circular letter there were six questions. The first was: How long after an applicant has recovered from a mild or catarrhal attack of appendicitis, before you consider him eligible for insurance?

Three companies replied: "We decline all, unless the appendix has been removed." Another answered: "Ten years." Another said: "Six months." The other companies variously fixed the limit between these two extremes. No two companies, excepting those which declined all, gave the same answers to the six questions submitted. For this wide difference in the rulings of the several companies I can offer no satisfactory explanation.

Many persons who have had appendicitis are now seeking life insurance, and no doubt the number will be much larger in the near future.

The question of the eligibility of this class of risks is one which is comparatively new to us, and its defini-

nite solution may not be possible at the present time. It may be necessary for us to wait until a larger clinical experience furnishes us with more accurate knowledge of the natural course and the ultimate outcome of the disease, or until the differences of opinion among the physicians and surgeons upon some of the points in its pathology, prognosis, and treatment have become settled. Even with the knowledge now at our command, we ought to agree upon some uniform mode of action, which will do neither injustice to the applicants nor to the companies which we represent.

I have not attempted to collect from the several companies the number of policy holders whose deaths were attributed to appendicitis and who had a history of having had the disease at the time of being insured, for I thought that even the combined experience of all the companies would be so limited that it would not be of much value for the purpose of this study.

I have seen no statistics showing the frequency with which inflammation of the appendix occurs. That it is quite common we all know. The statement often seen, that at least one-third of all post-mortems made upon adults at random give evidence of old inflammatory lesions of the appendix, indicates as clearly as anything the frequency of this ailment. Some of the expressions used by those surgeons who have so forcibly advocated early operations in all cases would lead us to infer that they believed that this disease was unusually frequent at the present time. It is generally thought, however, that more cases of appendicitis are seen nowadays than formerly, simply because the profession has learned to recognize its true nature.

It appears oftener in men than in women, four to one, according to Fitz' first series of cases, but in his second series the proportion is two to one. The Munich statistics, however, show relatively more women than men affected.

There are no observations which indicate the exact mortality of this affection. Fitz says: "The rate of mortality is by no means clearly established. The physician who sees only mild cases says it is low; while the surgeon who is called upon for aid in the gravest cases considers the mortality very high."

Bridges writes: "The mortality from appendicitis, considering the frequency of it, cannot be regarded as great. The mortality of those cases eventuating in perforation of the appendix is, however, great."

Richardson, of Boston, writes: "Excluding certain zymotic diseases, it causes more deaths than any other abdominal lesion. The number of deaths from appendicitis, in which the true cause is not even suspected, is, I have no doubt, very large. If we take the returns, however, and select those cases where death has been caused in males under forty by 'inflammation of the bowels,' we should get an approximate estimate of the number of deaths from this disease. It is only by collecting a large number of cases from many observers that the true death rate can be determined. This I have not attempted to do."

Let us look now at a few statistics. In his second series of cases, Fitz gave the number of those who died as 26 per cent. Porter, of Fort Wayne, collected 448

¹ Read before the Association of Life Insurance Medical Directors, May 1, 1896.

cases, in which the death rate was 17.23 per cent. Sahli reports 7,213 cases treated by 446 Swiss doctors; only 476 were operated on; of those not dealt with by operation only 8.8 per cent. died. Richardson gave me his personal experience in 401 cases, with a death rate of 13.4 per cent. Hawkins states the death rate of 264 cases admitted into the St. Thomas Hospital, London, as 14 per cent.

Ferguson says: "I see on an average about twenty cases of well-defined appendicitis each year, and out of this number about four would come to an operation. All the patients would get well, and the vast majority would remain well."

Bryant says: "Undoubtedly from sixty per cent. to eighty per cent. of the cases would recover from primary attacks without operation."

White writes: "Perhaps eighty per cent. of the cases of this type (catarrhal) recover under medical treatment. Of the remaining twenty per cent., at least one-half can be saved by operation during the condition of localized abscess, which occurs in probably that proportion of cases; of the remaining ten per cent., in which no protective adhesions would form, a certain indeterminate proportion recovers after operation, before septic peritonitis and intestinal paresis had occurred. This would leave a death rate of say five per cent. to eight per cent." (Wells).

If we examine the recent reports of those surgeons who believe that this disease should always be treated as a surgical one, and who have so vigorously pleaded for an operation in all cases as soon as a positive diagnosis has been made, we shall find that the death rate has been remarkably reduced. Deaver states that he has made two hundred consecutive operations, without any death; and Morris has recently published the results of one hundred consecutive operations, with only two deaths. These included all forms of the complaint. The reports of other surgeons show equally good results. Wyeth writes to me: "I have seen very few cases of death from relapsing appendicitis. I think this is accounted for by reason of the adhesions which form and include the first inflammatory focus, mechanically retarding the rapid infection of a recurring inflammation. I believe if every case of appendicitis were operated upon by a competent surgeon within twelve hours of the first symptoms of well-marked emigration of infectious organisms through the diseased or perforated wall, the death rate would not be over one per cent."

Richardson, who does not advocate operations in all cases, said to me that he had had seventy-five consecutive operations with no fatal results. Even general peritonitis, which is so much apprehended and dreaded as a result of an inflammation of the appendix, and which has always been considered to be almost surely fatal, until quite recently, has lost its terror in a measure, so that now a large per cent. of these cases recovers. McBurney has given us the records of his operations for diffuse suppurative peritonitis occurring as a result of appendicitis. Out of twenty-four cases, fourteen recovered. Albee saved three out of seven similar cases. Hawkins gives nine recoveries in thirty-six cases, some without operation. Richardson reports nine recoveries in thirty-two cases.

When we review the rapid progress made by the American surgeons in the treatment of this malady in the last few years, with its brilliant results in the saving of life, it is not unreasonable to anticipate that in the near future, with this improvement in the treatment still continuing, its death rate will become quite low.

I have dwelt upon this question of mortality because it is important that we should have a proper appreciation of the dangers to life resulting from appendicitis. Especially is this true when we consider the remark-

able tendency of this disease to return, and the possibility that the subsequent attacks may be followed by the same fatality as the primary one.

In studying this disease as affecting life-insurance risks, we need to recognize only non-suppurative and suppurative appendicitis.

Non-suppurative Appendicitis.—I will briefly review some of the essential features of this type of the disease. It has been stated by some observers that about eighty per cent. of all cases seen are of this form. The percentage of recoveries after the first attacks is variously given. Death is rare, and occurs only when general peritonitis or some other serious complication supervenes. The pathological changes in the appendix may be of the slightest, or they may be such as to leave the organ permanently diseased, or its lumen may become partially or completely obliterated, and the organ converted into a fibrous cord. It may be the seat of tuberculosis or other morbid conditions. Adhesions may be formed, of various extent and importance, which have been found to be the cause of some of the remote after-effects of the disease. There may be only one attack, or one or more subsequent attacks may occur at short or long intervals. Complete and permanent recovery may follow the primary or any of the succeeding attacks; or it may not take place until the appendix has been removed. Septic general peritonitis, or other serious complications, may appear. It is believed by many eminent surgeons that the appendix once severely or mildly inflamed is ever after a diseased structure, which is apt to give rise to serious trouble at any time in the future, and that it is a risk to the life of the patient to leave such an infected organ within the abdominal cavity. Many equally prominent in the profession have not accepted these extreme views.

It is in this variety that most of the relapses and recurrences are seen. Fowler states so clearly the distinction which should be made between the chronic relapsing and the recurring forms that I quote fully his words. He writes of the former: "The patient may become seemingly convalescent, in that all pain and febrile symptoms disappear. He may even be permitted to resume his vocation. Within a few weeks, or even earlier, a relapse takes place, with the symptoms perhaps more violent and threatening than at first. There is one symptom, at least, which does not entirely disappear, and its presence should always place the attendant upon his guard against this form of the affection. I allude to the symptom of persistent tenderness. This is sometimes accompanied by the presence of a tumor, although the latter is not an essential symptom of this type of the disease."

He says of recurring appendicitis: "The special feature of this form is the fact that the attacks occur at long or short intervals, suggesting some predisposing cause, which continues active after recovery from the first attack. It differs from the relapsing form of the disease in that entire recovery takes place. The patient remains free from any trace of the affection for varying periods, when suddenly and without any warning, he is subjected to another attack."

In some cases the interval between each succeeding attack becomes longer, its severity decreases, and finally the disorder ceases altogether, so that the patient is restored to health and is ever after as free from the risk of future trouble as if the appendix had been extirpated. This occurs when the lumen of the appendix has become completely obliterated. In those cases of appendicitis obliterans reported by Senn, in which ablation of the appendix showed only partial obliteration of its lumen, the relapses were frequent, and there was local discomfort or tenderness remaining during the intervals, as in the chronic relapsing form described by Fowler.

The two features of this type of appendicitis which make it of peculiar interest to life-insurance companies are its tendency to recur and its possibility of passing suddenly into the severe forms of the disease, either at the first or any subsequent attack.

The statistics showing the liability to second attacks are far from being satisfactory. The following figures will show the percentage of relapses and recurrences, as given by a few observers. Fitz, in his first series of cases, stated it as 11 per cent.; in his second series as 44 per cent., and in a recent conversation I had with him, he said: "A relapse is as likely to occur as not." Irish gave 50 per cent.; Richardson, 49.4 per cent.; Price, 50 per cent.; Ransohoff, 13 per cent.; Kraussold, 23 per cent.; Krafft, 22 per cent.; Porter, $9\frac{1}{2}$ per cent.; Bryant, 11 per cent. to 17 per cent.; Sahli, 20 per cent.; Gage, $33\frac{1}{2}$ per cent.

Gage writes: "Almost $33\frac{1}{2}$ per cent. of my cases had previous attacks. This is by no means equivalent to saying that $33\frac{1}{2}$ per cent. of all cases will have relapses, and I do not think this last proposition a fair one."

Mynter writes: "I firmly believe that a patient who has had one moderately severe attack is bound to get another sooner or later."

Morton writes: "A careful inquiry will usually demonstrate one or more relapses."

Meyer says: "It is the duty of the physician to follow up these cases, to determine how many remain actually well after one attack. I do not believe that twenty per cent.—no, not more than ten per cent., would be found to remain healthy."

Wyeth writes: "From clinical experience, it is known that a considerable number of cases of appendicitis, with more or less peritonitis and exudation, and at times with suppuration, undergo spontaneous resolution, the patient being usually restored to health, and living indefinitely without a recurrence of the disease. It may be safe to say that twenty per cent. of all cases have such a fortunate end."

I thought that if I could collect a large number of cases showing the exact time at which the second attack occurred, I should then be able to determine the time within which a majority of second attacks appeared. The published reports of cases do not give the exact time of the second attacks, except in a few instances. Probably there is stored up in the note books of the many observers just this information, and, if it were only accessible, it could be utilized in clearing up some of the doubtful points in this investigation. Accordingly, I wrote to several physicians and surgeons asking for such data. From their replies, and from those published cases which I have had time to examine, I have been able to collect 326 cases in which the exact time of the second attack was stated. In 210 cases, it appeared before six months; in 60 cases, between six months and one year; in 14 cases between one year and eighteen months; in 13 cases, between eighteen months and two years; in 11 cases, between two and three years; in 3 cases, between three and four years; in 2 cases, between four and five years; and in 13 cases, after five years.

From these figures, it is seen that 64.4 per cent. of the second attacks occurred before six months; 82.8 per cent. before one year; 87.1 per cent. before eighteen months; 91.1 per cent. before two years; 94.9 per cent. before four years; 96.5 per cent. before five years, and 3.3 per cent. after five years.

These statistics, so far as I know, are the only ones of the kind collected up to date, and they must be accepted as establishing the time within which second attacks have appeared. The study of a larger number of cases, no doubt, would alter these percentages somewhat, but still the fact would probably remain that in a large majority of the cases the relapses take place,

if they are going to occur at all, within two years after the primary lesion. The same opinion is expressed by those surgeons who replied to my question, without giving me exact data.

Cabot writes: "In regard to your second question, I should say usually, if a patient relapsed, he did so within a year, although I do not feel that I could lay down a positive rule in regard to this. In cases which have gone over two or three years, I should say I have almost never seen a relapse. My experience covers several hundred cases."

Morton writes: "From thirty days to a year or more."

Mixer says: "Within two years."

Gage says: "In my experience, a large majority has occurred within two years if at all, and mostly within one year."

The other replies received gave the number of relapses seen in each case, instead of the time of the second attack; so they are of no value for my purpose.

Suppurative Appendicitis.—It is in this variety that nearly all of the grave cases are seen, and they are usually the result of perforation of the appendix. Should this perforation take place before protective adhesions are formed, then general septic peritonitis is rapidly excited, with fatal consequences as a rule, or there may be diffuse peritonitis without perforation. It is this large death rate from peritonitis which makes this form of the disease so much dreaded, though with prompt surgical interference more cases recover now than in times past. When protective adhesions are formed before perforation occurs, then there is the formation of a localized abscess, the result of which, if relieved by skilful surgical aid, is almost always favorable. If the abscess is allowed to rupture itself, the course of the pus may be externally, or into some internal viscus, or into the peritoneum, causing diffuse peritonitis. In those cases in which the appendiceal abscess forms behind the cæcum (extra-peritoneal) the pus may pass in various directions. The most favorable place for the abscess to discharge is into the bowel, and next into the bladder. When into the former nearly all recover, and when into the latter, fifty per cent. In a large percentage of the cases, the appendix is so changed in character by the attack, or is so embedded and bound down in the adhesions, that no further harm can result to the patient. Again, the appendix may slough entirely away, and consequently the patient will be as exempt from a subsequent attack as if the organ had been excised.

In the circular letter sent to the physicians and surgeons, four questions were asked under the following head: In the suppurative cases, in which the abscess was opened and drained without the removal of the appendix,

(a) What has been the percentage of relapses in your cases?

(b) Within what time did the second attack appear?

(c) Have you seen more than one relapse in any one case?

(d) Is the subsequent attack as liable to be followed by so serious results as is the primary one?

I have transcribed the answers received.

(a) "Some have chronic infection, not assuming forms of attacks; others have acute exacerbations" (Morris). "None" (Mynter). "One in about twenty-seven cases" (McGuire). "None, so far as I know" (Homans). "I can recall two in seventy-five cases" (Gay). "In no case" (Morton). "Out of seventy-nine cases, four had return of the disease" (Richardson). "I have operated on at least two cases in which previous suppuration had occurred and had had an operation" (Stimson). "None" (Irish). "I cannot give the exact number, but I should say several" (Mixer). "Have had one case" (Gage).

"None" (Porter). "I have seen several relapses" (Cabot).

(b) "Two, two weeks after the operation; one, six weeks after, and one had four operations in nine years" (Richardson). Time not stated by Stimson. "Within a short time" (Porter). "Within six months" (McGuire). "Within a year" (Mixer). "Five years after the first operation" (Gage). "I cannot say within what time the second attacks appeared, but usually, I should say within a few months" (Cabot). "Two years, both cases" (Gay).

(c) "Yes, several" (Morris). "No" (McGuire, Homans, Gay, Porter, Mixer, Gage). "Yes, one had two relapses" (Stimson). "I have seen several relapses; in one case, certainly three" (Cabot).

(d) "I think so. It was certainly so in the two cases seen" (Stimson). "I should say that subsequent attacks usually appear as abscesses at a point along the old line of operation, and are, therefore, not so serious as in the first attacks" (Cabot). "I should think so" (McGuire). "No" (Porter). "No. General peritonitis is not likely to occur, because pus will travel along the old channels" (Gage). "Yes. No difference" (Morris). "No" (Mixer and Gay).

Richardson, in a recent conversation with me, said: "No. The most dangerous form is when the appendix hangs freely in the peritoneal cavity. In the abscess cases, as a rule, the appendix is bound down by adhesions, so that general peritonitis is not so likely to occur, and death following second attacks is rare."

It will be seen from the above answers that while several relapses have been observed, they cannot be said to be very frequent; that while two were stated to have appeared more than five years after the initial attacks, all the others were within two years, and most of them within a few months; and that, in the opinion of some of the surgeons, the subsequent attacks are as likely to be followed by the same serious consequences as in the primary one; but that others have expressed the belief that there is not this danger to be expected, and have very clearly given their reasons for this opinion.

In a recent discussion before the New York Surgical Society, Stimson said: "The generally accepted idea was that after one attack of suppurative appendicitis, sufficient changes were set up in the neighborhood to render the patient exempt from the risk of further attacks. Two cases had occurred to him recently, however, that indicated that this was not necessarily the case, since one patient, after what had been undoubtedly two attacks of suppurative inflammation, presented himself for the cure of a resulting hernia, and on operation it was found that the appendix was free within the peritoneal cavity, and practically devoid of adhesions."

Bryant and Fowler fully corroborated Stimson's statement, that frequently after an attack of suppurative appendicitis, the appendix was as fully capable of originating another attack as formerly. Rushmore was of the opinion that such cases did occasionally occur.

I have quoted this in full, because it gives quite clearly the two opposite views held by the profession upon this point, at the present time.

To my question: "Have you seen a recurrence in any form after the appendix had been excised?" I received one answer in the affirmative. Morris writes: "Yes, where more than one inch of the appendix was left in." A few cases have been reported of second attacks after the appendix had been removed, usually the result of improper treatment of the stump.

The Remote Complications and After-Effects.—A patient may have entirely recovered, to all appearances, from the immediate effects and complications of the disorder; still he is in danger of having certain

other sequelæ develop at any time in the future. The remote after-effects which are most frequently seen are an obstruction of the bowels in its various forms from adhesions, and peritoneal tuberculosis. Other sequelæ have been observed.

It is generally thought that adhesions once formed are permanent; but several operators have shown that when a second laparotomy has been required, as for the cure of a ventral hernia, the adhesions have been found in many instances to have disappeared.

If no symptoms of obstruction have appeared within a certain period after recovery, can we assume with any reasonable certainty that the probability of these symptoms developing at all is quite small? If so, at what time after recovery would you fix this limit?

To these questions, I received the following replies: Cabot: "I do not think we can ever rule out, with any certainty, the possibility of obstruction occurring a long time after an attack, as it is impossible to tell what bands have formed. It has been my experience, however, that adhesions usually disappear after the cause of irritation has been removed, so that, if a patient made a complete recovery, I should not expect any further trouble from adhesions after they had been a year in reasonable comfort." Homans says: "Yes. Perhaps one and a half years." Gage says: "Yes. I should think one year a liberal limit." Irish writes: "I have not seen a case of obstruction after recovery from operation." Morton says: "Yes. Quite safe at four or six months." Mynter says: "Yes. I believe there is very little probability of its developing." Morris writes: "Not without operation to determine the form of the adhesions." Porter says: "Yes. I think thirty days a safe limit." McGuire says: "Quite small after six months." Stimson says: "In cases operated on, with removal of the appendix, the chances of future trouble are very slight." Mixer says: "Yes. Two years." Gay says: "Yes. Six months." Richardson writes: "Yes. Six months."

The question, Would obstruction of the bowels be more likely to occur after a general than after a local peritonitis? was answered by a large majority of the surgeons in the negative.

It will be seen that, in the judgment of these observers, the probability of the obstruction of the bowels occurring after two years is very slight.

The danger of hernia following an operation in abscess cases is great, but in non-suppurative cases, when drainage is not required, this danger is quite small. A few cases of strangulation in this kind of hernia have been reported; though the possibility of such an occurrence is not large. The condition is one more of discomfort than of danger to the patient. The rupture can be entirely cured by a second operation as a rule.

Time will not permit me to consider tuberculosis of the appendix, or of the peritoneum, following this ailment; nor will I mention the other remote complications which may develop.

Of the other forms of abdominal disease which have been mistaken for appendicitis, it is not necessary for me now to speak. It is enough to recall to your mind that long list of morbid conditions given by Dennis, in which a wrong diagnosis was made.

Application to Life Insurance.—An applicant who has had appendicitis is an impaired risk, but with such a history he is not absolutely ineligible for insurance. Under what conditions is he insurable?

He should have completely recovered from the disease; in all other respects he should be up to the standard of physique and health usually required, and a sufficient time should have elapsed after the attack to show that the probability of the return of the trouble, or the development of any of its remote after-effects, is reasonably minimized.

To determine whether he has fully recovered from the ailment, we must rely wholly upon the opinion of our local medical examiner, and much will depend upon the care and thoroughness with which he makes the examination.

He should obtain a full history of the case, the date of the attack, the form of the disease, its severity and its treatment, whether there were any previous attacks or any symptoms which might be construed as such. He should inquire as to any symptoms of indigestion, pain, or constipation. He should scrutinize the abdomen with care for any evidence of tenderness remaining, of dilatation of the cæcum, of a hernia, of a fistula, or of tuberculosis. When practicable, he should employ the method recommended by Edebohls for the examination of the appendix. If the applicant is a female, then, in addition to the above, the condition of the uterus and its appendages should be carefully noted.

When possible, so much of his statement as relates to the history and treatment of the case should be corroborated by the attending physician or surgeon.

Many of our medical examiners have a proper appreciation of the importance of an attack of appendicitis from an insurance point of view, and obtain all the above facts and report them to the home office; but I am sorry to say that there are some examiners who merely make the statement that the applicant has had the ailment, without giving any further information.

It would seem advisable, therefore, in all cases of this class of risks, that a special letter of inquiry should be sent to the local examiner, requesting such details as may be desired.

How long after a person has recovered from an attack of appendicitis, before he should be considered eligible for insurance?

A different answer can be given to this question at the present time from what could have been made ten or even five years ago, for we have a more accurate knowledge of the natural history and prospective consequences of the disorder, and its proper method of treatment is better understood, and therefore more successful; so that the general results to the companies will undoubtedly be much more favorable now than formerly.

The following classification will probably include all of the different phases of the disease which we shall be called upon to decide as affecting life-insurance risks.

1. Cases of primary attacks of non-suppurative appendicitis, in which the appendix was not removed.

In this class of risks, the dangers to be guarded against are the return of the disease with its possibilities, and the development of some of its remote after-effects. The statistics show that the second attack occurred before one year in 82 per cent. of the cases, before two years in 91.1 per cent., before three years in 94.4 per cent., before four years in 94.9 per cent., before five years in 96.5 per cent., and after five years in 3.3 per cent.

Those surgeons who could not report their cases showing the exact time at which the second attack took place, but did give their impressions from the study of several hundred cases, used expressions on this point as follows: "We should say usually, if the patient relapsed, he did so within a year. In cases which have gone over two or three years, we should say we have almost never seen a relapse." They also expressed the opinion that if a patient went one year without any of the remote after-effects of the disease developing, the probability is quite small that they will appear later.

Now if the second attack takes place within two years in 91.1 per cent. of all the cases, there is less

than one out of ten chances that the disease will return after two years.

I have not been able to collect any reliable data showing the death rate in those cases which relapsed after two years. It certainly must be quite low. This statement is confirmed by several surgeons. It would seem reasonably safe, therefore, to accept this class of risks after two years.

2. Primary non-suppurative cases with the appendix excised.

In this class the recurrence of the disease is not to be expected, but the other remote after-effects are to be apprehended. It has been shown that the adhesions disappear in many instances after ablation of the appendix, consequently obstruction would not be so likely to occur as in the first class. Cases of this kind should be insurable after one year.

3. Suppurative cases in which the appendix has been extirpated, or in which it can be clearly proven that it has sloughed entirely away.

It may be very difficult to decide the latter point absolutely in some of the cases. The remote consequences from adhesions to be anticipated in this variety would be the same as those in class 2, and I can see no reason why the same rule should not be adopted for both classes.

4. Suppurative cases in which the abscess was opened and drained, the appendix not being removed.

From the data obtained, it appears that in this type of the disease a recurrence was observed in less than one out of twenty cases; and with only two exceptions the second attack occurred within two years, and mostly within a few months after the previous one.

While all of the authorities state that there is a possibility that any subsequent attack may be followed by serious consequences, still several surgeons who have had large experience with appendicitis inform me that, as a matter of fact, death is very rare after these relapses.

It would seem, therefore, that the risk of a fatal issue in any case after two years would be slight. Cases of this kind might be accepted for insurance after two years.

In those cases in which the abscess ruptures internally, each one must be judged upon its merits. Many of these cases make a perfect and permanent recovery, and are justly entitled to insurance.

5. Chronic relapsing and recurring cases.

An applicant with a history of chronic relapsing appendicitis would be barred from insurance, because he does not make a full recovery between the attacks. When it can be decided that in all probability the appendix has become obliterated, then he should be insurable. He should be required to wait three years after the last attack before he should be considered eligible.

I find it very difficult to arrive at any just conclusion in regard to those cases in which the recurrence has been at irregular intervals, the patient having been in perfect health and free from any symptoms of the disease between the attacks.

It has been stated that the patient appears to have some predisposition to the disease, and that the attacks are excited by errors in diet, overexertion, etc., or there is an underlying rheumatic or gouty tendency, as when the ailment has occurred in more than one member of the same family.

This type, as a rule, is not liable to pass suddenly into the grave forms of the disorder. If a person gives a history of two or more attacks, at periods of less than five years apart, he should be declined; but when he has gone over five years without a recurrence, it is a question in my mind whether we should be assuming any more risk in accepting such a case than we take every day in some other diseases. Each case,

however, must be judged according to the facts submitted. The age of the applicant would be an important factor in enabling us to form a decision.

6. Cases which have recovered from general peritonitis, either with or without an operation, the appendix having been excised or not.

It is generally thought that very few patients survive such an attack, but recovery does occur; and under modern treatment the number which gets well is increasing. Are the remote consequences of adhesions more likely to develop after a general than after a local peritonitis? Upon the answer to this question we should base our decision as to the eligibility of this class of risks.

The replies received from the majority of those surgeons to whom this question was addressed, indicate that there is no difference in the liability between the two forms of peritonitis. Whether there is greater danger of the development of some of the other remote after-effects, as abdominal tuberculosis, after a general than after a local peritonitis, I have no means of knowing. With the appendix unremoved, second attacks of peritonitis have been observed. Richardson reports a fatal case which occurred three years after the first peritonitis.

I can see no good reason why the same rules should not govern this class as those given for classes 1 and 2, excepting that a patient who has had a severe attack of general peritonitis has a protracted convalescence as a rule, and therefore a longer time would be required to establish perfect health than after a milder form of the disease; and, besides, there may be a greater risk in this class of cases.

Taking the above facts as a basis upon which to form an opinion, I should say that cases of this class were eligible for insurance after one year when the appendix has been excised, and after three years when it has not been removed.

7. Cases of hernia following an operation.

These should be classified with other kinds of hernia, though it has been said that strangulation is not so liable to occur in this type as in the other varieties. The applicant should be required to wear a suitable support.

The above recommendations seem to be justified by the facts obtained from studying the literature of appendicitis, and from the opinions expressed by those physicians and surgeons who have so kindly given me the benefit of their large experience with the disease.

The rule "to decline all applicants with a history of appendicitis, unless the appendix has been removed," is, in my judgment too stringent; and, on the other hand, the rule to accept an applicant after six months with such a history, the appendix not having been excised, is too liberal, as it is assuming too great a risk, excepting perhaps in the very mildest cases of the disease.

While the former rule may more safely guard the company, so far as the death rate is concerned, it will at the same time deprive many persons of the benefits of insurance to which they are justly entitled; and, besides, it will turn away an amount of business which should be retained.

The company may often suffer as much injury when an injustice is done to the applicant, as when by an error of judgment a doubtful risk is approved.

I am not strenuous that these recommendations shall be adopted by the association in just the form submitted; but it is my earnest hope that we may be able to formulate some rules which will be uniformly used by all the companies in dealing with this class of risks.

Epistaxis may often be controlled by snuffing into the nostrils a saturated solution of antipyrin.

MESCAL BUTTONS.¹

ANHALONIUM LEWINII—HENNINGS (LOPHOPHORA WILLIAMSII LEWINII—COULTER).

By D. W. PRENTISS, A.M., M.D.,

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, MEDICAL DEPARTMENT OF COLUMBIAN UNIVERSITY,

AND

FRANCIS P. MORGAN, A.B., M.D.,

PROFESSOR OF PHARMACOLOGY, MEDICAL DEPARTMENT OF COLUMBIAN UNIVERSITY, WASHINGTON, D. C.

THE study of *Anhalonium Lewinii* is of comparatively recent date, the subject having been brought to the attention of the medical world in 1888 by Dr. Lewin, of Berlin, who published at that time the results of his observations upon the drug. In 1894 Drs. Lewin and Heffter, of Germany, reported the results of further study of the subject. In 1891 James Mooney, of the United States bureau of ethnology, in a paper read before the Anthropological Society of Washington, first brought to public attention the remarkable religious ceremonial use of the plant by the Kiowas and other tribes of the Southern plains, among whom he had been conducting researches for some time. In 1894 he brought back to Washington for examination a large quantity of mescal, under the belief that investigation would corroborate the claim of the Indians as to its valuable medicinal properties. This was given over to Mr. E. E. Ewell, of the department of agriculture for chemical analysis, and to the writers for therapeutic test. Our study of the subject has shown that the mescal buttons possess properties which are remarkable, the exact likeness of which is not found in any other known drug, and also that it possesses virtues which, when applied in the treatment of certain diseased conditions, may prove the drug a valuable addition to our present list of therapeutic agents. It is for these reasons that we have chosen to present this subject in this paper for your consideration.

Anhalonium Lewinii is a plant belonging to the natural order of Cactaceæ or cacti, as they are commonly called. One of the divisions of this great order is the genus *Anhalonium*, of which there are several species, and among them *Anhalonium Williamsii*, and the one now under consideration, *Anhalonium Lewinii*.

As to the exact place in botanical classification which the *Anhalonium Lewinii* should occupy, there is some difference of opinion among botanists. Hennings,² who first published an accurate description of the plant, believed it to be a separate species of the genus *Anhalonium*. Dr. A. Heffter³ holds the same view, reasoning both from botanical characteristics and the dissimilarity in physiological action between the *Anhalonium Williamsii* and *Anhalonium Lewinii*. On the other hand, botanists who have investigated the subject more recently hold that the *Anhalonium Lewinii* is but a variety of the species *Anhalonium Williamsii*. Coulter, an authority upon the cacti, holds this view and gives the plant the name *Lophophora Williamsii Lewinii*.⁴ The botanist in charge of the United States botanical gardens in Washington believes that the two plants belong to the same species.

The *Anhalonium Lewinii* inhabits portions of the valleys of the Rio Grande and Pecos rivers in Texas and New Mexico, growing in barren, rocky soil, and often in places which can be reached only with difficulty by those who gather it. It reaches a height of about one inch above the surface of the ground. The

body (Fig. 1) is comparatively thick, and is surmounted by a top, which is composed mainly of the blunt leaves of the plant. In the centre of this top is a tuft about one-half to one inch in diameter, composed of yellowish-white filaments or hairs. These

FIG. 1.

tops, when dried, constitute the mescal buttons, the commercial form of *Anhalonium Lewinii*.

The mescal buttons (Fig. 2) are of a brown color, circular, about one-half to one and a half inches in diameter and one-fourth of an inch in thickness. The edge curls upward, giving to the under surface a con-

FIG. 2.

vex appearance. In the centre of the upper surface is a tuft composed of the yellowish-white hairs before mentioned, and matted down so as just about to reach the level of the upturned edge. The buttons vary in weight from about one to eight grams, the average being about four grams.

The button is somewhat brittle and hard and can be pulverized in a mortar with difficulty. In the mouth, however, under the action of the saliva, it swells and rapidly becomes soft, the consistency which it acquires giving somewhat the sensation imparted by slippery elm. The taste is disagreeable and nauseous and very bitter, with a persistent after-taste. A marked sensation of stinging or tingling is produced in the fauces, which remains for some time after the drug has been swallowed. The powdered drug is odorless when dry, but acquires a nauseous odor upon being moistened.¹

Physiological Action.—In connection with the physiological action of the mescal, its use by the Indians is of great interest. The Kiowa Indians and their associated tribes, formerly ranging from the Arkansas River southward into Mexico, have, from the earliest period, made its use a regular part of their religious ceremonies. When finally gathered upon the Kiowa reservation in Oklahoma, which they now occupy, they continued the use of the buttons in their ceremonies, the demand being supplied by traders who obtain it from the valley of the Rio Grande. Its use has spread to such an extent that the rite has become the chief religion of all the tribes of the Southern plains. Complaint being made to the government authorities at Washington by missionaries and others, the eating of the drug was rendered unlawful and was forbidden under severe penalties. Nevertheless, the use of the mescal has persisted to the present time.

The religious ceremony, as described by Mr. Mooney, who has participated in it several times, usually takes place on Saturday night. The men seat themselves in a circle within the tent, around a large fire which is kept burning brightly. After a prayer the leader hands each man four buttons, and each, having been freed from the tuft of hairs, is put into the mouth and, after it is thoroughly softened, is ejected into the palm of the hand, rolled into a bolus, and swallowed. At midnight each man calls for as many mescals as he wants, and in this way ten or twelve of the buttons, as a rule, are taken at intervals between sundown and daybreak. They sit quietly throughout the ceremony, while the fire is kept burning brightly and a continual singing and beating upon the drum is kept up. Most of the time they are in a state of reverie, the intoxication of the drug showing itself in the visions of color and other manifestations which will be described later. The hours are interspersed with songs, prayers for the sick, and baptismal rites. They sit thus from sundown to nearly noon of the next day. At the close of the ceremony they go out, it is claimed, without the slightest depression or unpleasant after-effect. Upon the day following the ceremony they carefully abstain from the use of common salt with their food: this, it seems, for a religious reason, and not because of any incompatibility of salt with the drug or its effects.²

To determine the physiological action of the crude drug—the mescal buttons themselves—upon the human system, they were administered in varying quantity to different young men who kindly volunteered their services for the purpose. Eight of these experiments were made, and in each enough of the drug was given to produce decided characteristic symptoms. Observations were taken at frequent and regular intervals to ascertain the effects upon the different portions of the body. Most of these experiments have been reported in full,³ but time does not permit us to give a detailed account of them. The following are briefly the results obtained:

¹ The writers, in *Therapeutic Gazette*, September, 1895.

² See also "Mescal Plant and Ceremony," James Mooney, *Therapeutic Gazette*.

³ *Therapeutic Gazette*, September, 1895.

The most remarkable of the physiological effects of the drug was the production of visions. These appeared in most cases after three of the buttons had been taken. The visions ranged from ill-defined flashes of color to most beautiful figures, forms, landscapes—in fact there seemed to be absolutely no limit to the variety of visions which the drug could produce. They could in but few cases be seen with the eyes open, but upon closing them an ever-changing panorama appeared. Drumming, or otherwise marking regular time, had a marked effect upon the visions—much enhancing the beauty and variety of the objects seen. The fact is of interest in connection with Mr. Mooney's statement that during the eating of the mescal by the Indians there is kept up a continual beating upon the drum. In three cases the visions were under the control of the will, and in two they were subject to the suggestion of others. The effect of the drug in the production of visions is probably due to stimulation of the centres of vision in the brain. The persistent ache and feeling of exhaustion in the occipital region, which persisted for several days after one of the experiments, is of interest in this connection.

A clearer idea of the nature of these visions is given by the following extract from one of the cases already reported. In all other cases, similar effects were produced. "The first sensations that followed my taking the drug came upon thoughtlessly closing my eyes. Instantly there sprang into the field of view a host of little tubes of shining light, down which green and red balls the size of peas were constantly rolling. The tubes of light bent themselves into the shape of letters, but they would spell nothing, and, slowly curving themselves into grotesque shapes, began to revolve rapidly, the green and red balls going in the opposite direction with even greater velocity. All the field of view between these silent wheels was filled in with a shifting mass of green. The colors were wonderful. They were the colors of the spectrum intensified as though bathed in the fiercest sunlight. No words can give an idea of their intensity or of their ceaseless, persistent motion. The figures constantly changed in form and color, but always remained a series of fantastic curves, revolving rapidly back and forth upon their own axis. The forms changed through rich arabesques, Syrian-carpet patterns, and plain geometric figures, and with each new form came a new flush of color, every shade appearing, from pure white to deepest purple. When the eyes opened and the light was turned up, the visions faded like stars going out in daylight, and the room, tables, chairs, and all surroundings came back into real existence and within reach of the hands."

It will be seen that the predominating hallucinations are the wonderful color phenomena, although the figures, forms, etc., are in themselves sources of pleasure and admiration.

In some cases no effect whatever was produced upon the reason or will of the individual. In others, there was some slowness of thought and loss of power of expression, and in one of the experiments a marked delusion. Compared with other drugs of this class, however, the effect upon the mind is extremely slight.

Dilatation of the pupil was well marked in every case, and persisted for from twelve to twenty-four hours after the drug was taken. The dilatation was accompanied by a slight loss of the power of accommodation and consequent disturbance of vision.

More or less depression of the muscular system existed in every case, and this was the first effect noticed after the drug was taken. It ranged from a feeling of lazy contentment to marked muscular depression. Susceptibility to this effect varied widely. Whether the sedative effect is produced by action on the nerve

centres, peripheral nerves, or their nerve endings, or on the muscular fibres themselves is not yet determined, but indications point to action through the nerve centres.

Partial anæsthesia of the skin was present in three of the cases, appearing when the effects of the drug began to wear off.

The heart action is at first rendered slower and stronger. This is followed by a rise to the normal, which continues during the period of greatest activity of the drug. In the cases in which the muscular depression was greatest, slight if any depression of the heart was present.

The respiration was unaffected in all cases but one. In this it seemed to partake slightly of the general muscular depression.

Upon the stomach the drug produced an effect which varied from a feeling of uneasiness and fulness at intervals, to nausea and vomiting.

Inability to sleep for at least twelve hours after the influence of the drug passed off was a uniform effect.

Appreciation of the duration of time was lost in all cases—as in the effect of *cannabis indica*. In one case a snowstorm appeared to last an hour, although in fact the vision continued not more than one minute.

No constant effect upon the bowels, skin, temperature, or secretion of the various glands of the body was found.¹

The only record of the taking of *Anhalonium Lewinii* for experimental purposes which we have been able to find is that of Briggs.² He took "a third of a specimen," and the symptoms produced were the following: In fifteen minutes the pulse rose from 60 to 70. In thirty minutes there was fulness of the head, pulse 90, respiration 26. The sense of fulness increased, and was followed by a headache and swimming in the head. Suddenly the pulse shot up to 160, and the respiration increased so that he could with difficulty get sufficient breath to keep himself alive. He thought he was about to die, and became unconscious. In six to eight hours his pulse and respiration went down again to the normal. Great depression existed for twelve hours.

The symptoms produced in this experiment are so widely different from those which we have obtained from administration of the drug that we cannot believe that the drug taken by Briggs was the same one which we have now under consideration.

Lewin,³ in experiments upon animals, found that in them the drug produced an acute muscular spasm of varying intensity, with increased reflexes, its action in this particular much resembling that of strychnine or brucine. No such effect was present, however, in our experiments upon man. Whether or not it would be produced by much larger doses is, of course, a matter of conjecture. In some animals, also, a quickened respiration was noted, which effect was present in our experiments only in one case, and in the presence of great general muscular depression. In animals, also, the heart remained unaffected, whereas in man we found a primary slowing of the heart action. In both animals and man more or less tendency to nausea and vomiting existed in most cases.

The physiological action of *Anhalonium Lewinii* upon man cannot be said to be identical with that of any other known drug. Its effects resemble those of certain drugs in some of the symptoms produced, but differ widely from them in others. *Cannabis indica* produces visions, with dilated pupils and with slight effect upon the circulation. In these particulars its ac-

³ Archiv für experimentelle Pathologie und Pharmacologie, Band xxxiv., Heft 5 u. 6.

tion is similar to that of *Anhalonium Lewinii*. But *Cannabis indica* is a hypnotic, and the delirium and hallucinations are in most cases followed by sleep. *Anhalonium Lewinii*, on the other hand, tends to produce wakefulness in every case. The Indians do not sleep for twenty-four hours after the commencement of their ceremony, and in our experiments sleep was found to be impossible for about the same length of time.

In this tendency to produce wakefulness it resembles cocaine. The visions produced by *Cannabis in-*

but Mr. Ewell believes that the former is but an impure hydrochlorate.

Lewin¹ describes anhalonine sulphate as forming needle-like crystals, colorless or of a slightly yellowish tinge; easily soluble in cold water, but much more so in hot water; almost insoluble in alcohol and ether.

The physiological action of anhalonine upon guinea-pigs and other small animals has been investigated by Lewin and Heffter. Lewin found that in these animals the alkaloid produced at first a primary collapsed condition, which was followed by an increase in the reflex excitability, and, if the dose administered was large enough, convulsions which resembled to a certain extent those produced by strychnine. The action of the drug, so far as these experiments would indicate, is somewhat analogous to that of strychnine. The lethal dose was found to be 0.16 to 0.20 gram per kilogram of body weight.

These results we have verified by a series of experiments upon guinea-pigs in the laboratory. The following experiment is fairly typical.

Guinea-pig; weight, four hundred and twenty-five grams.

1:01. Injected 0.05 gram anhalonine hydrochlorate in solution.

1:03. Tremor of body.

1:05. Tremor of body. Opisthotonos, followed by convulsion.

1:08. Slight convulsion. Pulls itself around by front legs; hind seem paralyzed. Opisthotonos.

1:10. Convulsion on touch.

1:12. Breathing rapid. Tremor of front extremities.

1:15. Attempts to move but cannot, except extremities.

1:25 to 1:40. Constant convulsive movements of whole body. Normal reflex to touch, breath-of-air sound, etc., exaggerated.

1:30. Biting and chewing. Opisthotonos.

1:40. On feet. Condition better. No tremor or convulsions.

1:45. Convulsion, precipitated by rubbing back. After it, legs extended for a short time.

1:47. Sits up. From this time gradually improved.

In order to ascertain the action of anhalonine upon man, Dr. Morgan took the drug in progressively increasing doses daily up to 0.20 gram without any appreciable effect. As this amount is nearly four times the quantity of anhalonine contained in the crude drug administered in the experiment already reported, it is evident that anhalonine cannot be the active principle of mescal buttons, or even a potent factor in the production of their effects. A second alkaloid has also been obtained from *Anhalonium Lewinii*,² and was called by Heffter alkaloid B. This, for convenience, we shall call mescaline. Its formula, crystalline form, solubility, etc., are now being made a subject of study by Mr. Ewell. It is soluble in ether, chloroform, and petroleum ether. In the last it is much more sparingly soluble than is anhalonine. It forms a hydrochlorate with hydrochloric acid.

Mescaline hydrochlorate is a white substance, forming tabular crystals. It is much more soluble in water and alcohol than is anhalonine hydrochlorate.

² Dr. A. Heffter: Arch. f. exper. Path. u. Phar., 1894, xxxiv., 66.

FIG. 3.

dica "are generally of a gay character, producing much merriment, accompanied by a great inclination to muscular movement."¹ The visions of *Anhalonium Lewinii* provoked wonder and admiration, but no merriment, and there was present disinclination to make any muscular effort. Other marked differences exist, which will become evident to any one comparing the action of the two drugs.²

Alkaloids of *Anhalonium Lewinii*.—In 1888 Lewin subjected the mescal buttons to analysis and succeeded, by chemical methods which need not be given here, in obtaining an alkaloidal substance, to which he gave the name anhalonine, and to which he ascribed the chemical formula $C_{12}H_{16}NO_2$. Mr. Ewell,³ who has succeeded in obtaining anhalonine in a pure state, describes it as a white strongly alkaline substance. It crystallizes from aqueous solution in prismatic, sometimes tabular crystals of the rhombic system. It is soluble in a large quantity of water, and is unusually soluble in alcohol, ether, chloroform, benzine, and petroleum ether. Its melting-point is $77.5^{\circ}C.$, and it can be sublimed without decomposition. It forms salts with the ordinary acids.

Anhalonine hydrochlorate (Fig. 3), which was used in our experiments with the first alkaloid, is a white, odorless substance forming needle-like crystals. It is soluble in water in the proportion of two parts per one hundred. The solution is very bitter to the taste. The hydrochlorate is also soluble in alcohol. It melts at 254° – $255^{\circ}C.$ with decomposition. It rotates the plane of polarized light to the left. Lewin describes an amorphous as well as a crystalline hydrochlorate,

³ I am indebted to Mr. E. E. Ewell, Bureau of Chemistry, U. S. Department of Agriculture, for the chemical description of the constituents of mescal buttons and the photographs reproduced in this article.

FIG. 4.—Third Alkaloid. $\times 60$ diameters.

We have conducted a series of experiments upon guinea-pigs to determine as nearly as possible the characteristic effects of mescaline, and in what particulars its action differs from that of anhalonine.

I.—Guinea-pig; weight, five hundred and seventy-six grams; 0.01 gram mescaline hydrochlorate in solution, hypodermically. No appreciable effect. Later, 0.02 gram injected in same animal. No decided effect. Seemed more sluggish in movement and less easily frightened than normally. Breathing more rapid.

II.—Guinea-pig; weight, four hundred and twenty-five grams.

12:15 P.M. 0.03 gram mescaline hydrochlorate, hypodermically into inner side of thigh.

12:19. In corner. Apparently drowsy. Will not move when struck.

12:23. Tremor of head and body.

12:28. Most rapid convulsive movements of extremities, as if running, but makes little progress, as feet seem to take no hold upon floor.

12:30. Quiet, on belly, in natural position.

12:43. Same; seems drowsy. Recovery from this time.

III.—Guinea-pig; weight, four hundred and sixteen grams.

12:53. 0.04 gram mescaline hydrochlorate in solution, hypodermically.

12:57. Runs around uneasily. Rapid chewing-movements of jaw.

12:58. Pupil slightly dilated. Chews rapidly. Tremor of head.

12:59. Runs around in frightened manner, with tremor of body. Chews. Breathing rapid.

1:00. Runs around, jumps high, and falls on side in convulsion. Extremities stiff. Opisthotonos.

1:01. On feet again. Tremor. Breathing rapid.

1:02. Pupil dilated. Breathing rapid and labored.

1:05. Violent convulsion.

1:06. More quiet. Tremor.

1:11. Looks around more normally. Breathing 150 per minute and difficult. Whole body shakes.

1:16. Moves backward. Breathing same.

1:20. Breathing 120 per minute. Walks backward.

1:33. Runs backward around cage.

1:40. Breathing 104, but more irregular.

2:10. Walks backward. Breathing much slower, but weak and irregular.

3:00. Animal bright and runs forward when touched suddenly. Recovery.

IV.—Guinea-pig.

1:00. 0.047 gram mescaline hydrochlorate in solution, hypodermically.

1:03. Frightened and restless. Breathing rapid.

1:04. Rapid chewing-movement at intervals.

1:05. Very restless. Tremor on moving. Respiration irregular and labored.

1:06. Cries out. Runs around at intervals.

1:08. Jumps up and falls on side in convulsion. Extremities rigid.

1:08½. Gasping on side.

1:10. Respiration ceased.

1:13. Thorax and abdomen opened. Auricles and ventricles found beating, but not synchronously. Auricles beating rhythmically at 60 per minute. Ventricles, 26 per minute.

1:27. Ventricles 24 per minute and very weak. Two drops ten-per-cent. solution mescaline hydrochlorate dropped upon heart. Beats become more rapid and stronger than before, and continue so for several minutes.

1:38. Ventricles, 42 per minutes.

1:47. Heart ceases to beat thirty-seven minutes after breathing ceased. Cavities dilated and filled

with dark blood. Pupils dilated to maximum extent. Lethal dose in this experiment, 0.12 per kilogram of body weight of animal.

V.—Guinea-pig; weight, three hundred and eight grams.

12:09. 0.054 gram mescaline hydrochlorate in solution, hypodermically.

12:10. Tremor of body. Increased restlessness. Runs around.

12:11. Restless. Convulsion, as in last experiment.

12:13. Convulsive movements continue. Pupils dilated.

12:14. Gasping on side.

12:16. Dead. At autopsy pupils found dilated to maximum extent. Heart stopped in diastole; cavities filled with dark blood. Lethal dose in this experiment, 0.17 per kilogram.

Experiments with mescaline hydrochlorate upon kittens gave practically the same results. The pupil was dilated even by small doses. The breathing soon became very rapid and shallow. Convulsions similar to the ones above reported were produced, and the heart continued to beat after respiration had ceased. The lethal dose was found to be practically the same. The most important difference in effect was that in kittens the drug seemed to act from the very first to depress the muscular system, the animals resting throughout the experiments upon the belly, the extremities extended flat upon the table. They attempted to move around, but could not.

It is evident from these experiments that the effects of mescaline are widely different from those of anhalonine. The minimum lethal dose of mescaline in our experiments as found to be 0.12 per kilogram, whereas Lewin found the lethal dose of anhalonine to be 0.16 to 0.20 per kilogram.

While both alkaloids in large doses produce convulsions, those of mescaline are different in character from those produced by anhalonine. As already stated, the convulsions of anhalonine somewhat resemble those occurring in strychnine poisoning. They are accompanied by some increase in the reflex excitability and more or less opisthotonos, and they can be brought on by external stimulation. While the animal under the influence of mescaline exhibits at times great restlessness, nevertheless the effects are not accompanied by increased reflex excitability and the animal appears rather less responsive to external stimulation than normally, and convulsions cannot be precipitated by such stimulation. Opisthotonos also is not a marked feature of the full effects of the alkaloid, although it is present to a slight degree during the convulsions.

It would appear that the convulsions produced by mescaline more closely resemble those caused by non-oxygenation of the blood. The effects of the alkaloid are accompanied by rapid and difficult breathing and symptoms of respiratory embarrassment. In experiment III. this was true to such an extent that all the muscles of the body seemed to be brought into play to aid the animal in obtaining sufficient air, and the appearance presented was that of intense dyspnoea. Death also is preceded by respiratory failure, the heart continuing to beat for a variable length of time after the breathing ceases. After death the ventricles are found dilated and filled with dark blood. Furthermore, Heffter,¹ who made a limited number of experiments with this alkaloid upon frogs, makes no mention of convulsions as an effect of the drug in that class of animals; whereas in our experiments upon animals of higher development, convulsions were a constant symptom when the drug was administered in large dose. This alone would lead us to believe that

¹ Archiv f. exper. Path. u. Phar., 1894, 34, 65.

the convulsions produced by mescaline are asphyxial in character and produced by contact of the non-oxygenated blood with the motor-nerve centres, it being a well-known fact that asphyxial convulsions do not occur in frogs, whereas they do occur in animals of higher development. Brunton¹ states that if any drug produces convulsions in the higher animals and not in frogs, the probability is that the convulsions it produces are asphyxial, and not due to direct irritant effect of the drug upon the motor centres. This, taken in connection with the facts already stated, leads us to believe that the convulsions produced by mescaline are asphyxial in character.

From these experiments it is also evident that mescaline has no influence upon the heart as a depressant, even when administered in fatal doses.

When given hypodermically it acts to dilate the pupil. No effect upon the pupil was obtained by dropping a five or ten per cent. solution of the hydrochlorate into the eye.

The alkaloid appears to depress the muscular system and the respiration.

In its constitutional effects, mescaline much resembles cocaine, and the similarity in action will at once become apparent in comparison with the effects of the latter drug upon the lower animals.²

From the mother liquor left after the separation of anhalonine and mescaline, Mr. Ewell has succeeded in obtaining a third alkaloid, entirely different in its chemical and physiological properties from the two already considered. The hydrochlorate of this third alkaloid, which was the salt used in our experiments, is white or of a slightly yellowish color. It forms nodular groups of radiating needle-like crystals (Fig. 4) which are readily soluble in water and alcohol. The taste of the crystals is acrid and slightly bitter, with a persistent after-taste. Its reaction is neutral.

We have performed a series of experiments upon the lower animals to determine so far as possible the physiological effects of this alkaloid.

I.—Rabbit; weight nine hundred and eighty-five grams.

11:55. 0.0133 gram hydrochlorate of alkaloid 3 in solution, hypodermically.

11:56. Restless. Great tremor. Animal rises upon four extremities, which are perfectly rigid, and pointing outward from body like the legs of a "sawhorse," and seems to be propelled slowly around table by violence of tremor.

11:57. Quiet, on belly, hind legs flat on table. On touch, extremities become rigid and violent tremor appears.

11:58. On feet, with rigid extremities and tremor as above.

11:59. Breathing rapid. Quiet if not touched. On touch, convulsive movements.

12:02. Breathing very rapid. Heart 156 per minute.

12:05. Breathing same. No convulsive movements on touch. Hind legs flat on table.

12:07. Hops fairly normally, using back legs awkwardly. Recovery from this time, breathing and heart gradually becoming slower to normal. Amount injected in this experiment, 0.0136 per kilogram of body weight.

II.—Rabbit; weight, five hundred and twelve grams.

12:07½. 0.01 gram hydrochlorate of alkaloid 3 in solution, hypodermically.

12:08. Tremor, especially of hind extremities.

12:09. Violent tremor. In hopping, hind legs somewhat stiff. Breathing rapid.

12:10½. "Sawhorse" phenomenon as in last ex-

periment lasting about ten seconds, after which, animal fell on side in tetanic convulsion. All muscles rigidly contracted. Opisthotonos, and extension of extremities. Followed by gradual relaxation of all muscles.

12:11. Muscles flaccid. Breathing ceased. Lethal dose in this experiment, 0.02 per kilogram.

III.—Rabbit; weight, one thousand one hundred and sixty-five grams.

2:19½. 0.03 gram hydrochlorate of alkaloid 3 in solution, hypodermically.

2:21. Tremor of body.

12:21½. Tremor so violent as almost to amount to convulsive movement.

12:22. "Sawhorse" phenomenon, as in preceding experiments, after which animal fell on side. Convulsive movements. Rigid extremities. Opisthotonos.

12:22½. Gradual relaxation. Breathing found to have ceased.

12:35. Thorax opened. Heart still beating. Heart ceased in diastole, twenty-seven minutes after breathing stopped. Lethal dose in this experiment, 0.025 per kilogram.

IV.—Rabbit; weight, four hundred and seventy-six grams.

11:37. 0.025 gram hydrochlorate of alkaloid 3 in solution, hypodermically.

11:38. Violent tremor. Jumped up and fell on side in convulsions. Opisthotonos, extremities extended, and all muscles rigid. No movement.

11:39. Convulsive twitchings. Gradual relaxation.

11:40. Breathing ceased.

11:45. Thorax opened. Heart beating rhythmically, 21 per minute.

11:50. Heart beating more slowly. Finally stopped in diastole.

Lethal dose in this experiment, 0.053 per kilogram.

In guinea-pigs the alkaloid produced effects very similar to those produced in rabbits.

V.—Guinea-pig; weight, seven hundred and eight grams.

12:29. 0.007 hydrochlorate of alkaloid 3 in solution, hypodermically.

12:31. Slight tremor of ears.

12:34. Much startled by sudden noise, as rapping table with pencil.

12:41. Same. Restless.

12:47. Quiet. Jumps clear from table when blown upon, or upon sharp noise.

12:51. Same. Cries on being touched. Runs awkwardly with violent tremor.

12:53. Increased reflex excitability continues. Not frightened by object brought rapidly toward it. Condition remained as described until 1.09 when it gradually became normal. Amount injected in this experiment, 0.01 per kilogram.

VI.—Guinea-pig; weight, seven hundred and thirteen grams.

11:45. 0.0196 gram hydrochlorate of alkaloid 3 in solution, hypodermically.

11:46½. Slight tremor. Runs around.

11:48. Violent tremor, especially on moving.

11:50. Violent tremor. Falls on side. Muscles of body and extremities contracted and rigid. Extremities extended. Opisthotonos.

11:50½. Gradual relaxation. Hair on fore part of body "on end."

11:51 to 11:55. Alternating tetanic spasms and relaxation. Breathing absent during spasm, accelerated during intervals.

11:56½. Animal on side. Constant spasmodic twitchings of head, body, and extremities, continuing until

¹ "Pharmacology, Materia Medica, and Therapeutics," pp. 159 and 237.

² See H. C. Wood: "Therapeutics, Its Principles and Practice."

12:05. Heart and breathing rapid. Tetanic spasms can be precipitated by touch or irritation.

12:05½. Tetanic convulsion followed by relaxation.

12:06. Gasping. Breathing gradually becomes regular and slower.

12:09. Can stand on feet. Hair still "on end."

12:11. Moves around awkwardly. Recovery. Amount injected in this experiment, 0.0275 per kilogram.

VII.—Guinea-pig; weight, six hundred and eight grams.

12:00. 0.0182 gram hydrochlorate of alkaloid 3 in solution, hypodermically.

12:02. Tremor on moving.

12:04. Tetanic convulsion. Extremities extended. Opisthotonos, followed by relaxation. Hair on fore part of body "on end."

12:05 to 12:10. Alternating tetanic spasms and relaxation.

12:10. Gasping. Opisthotonos.

12:12. Tremor. Spasmodic twitchings.

12:14. Same.

12:20. Heart rapid, breathing fairly normal.

12:26. Tetanic convulsion brought on by touch, followed by gradual relaxation. Breathing found to have ceased.

12:30. Thorax opened. Heart still beating.

12:50. Heart ceases. Lethal dose in this experiment, 0.03 per kilogram.

In frogs effects were produced which even more clearly indicate the physiological action of the alkaloid under consideration. These effects were similar to those produced in guinea-pigs and rabbits. A series of experiments upon frogs was made, of which the following may be considered typical:

VIII.—Frog; weight, one hundred and eighty-three grams.

2:33. 0.00549 gram hydrochlorate of alkaloid 3 in solution, hypodermically.

2:37. Increased reflex excitability to touch.

2:39. Reflex excitability still more increased. Violent sudden extension of extremities on touch.

2:44. Tetanic convulsion on touch, or other slight irritation. Animal lies perfectly quiet; when touched, however, tetanic convulsion appears, with contraction and rigidity of all muscles and extension of extremities, which lasts for a few seconds, followed by relaxation and quiet until again irritated.

Condition remained same for several hours, and it was dead upon following morning. Lethal dose in this experiment, 0.03 per kilogram.

IX.—Frog; weight, two hundred and sixty-eight grams.

12:02. 0.008 gram hydrochlorate of alkaloid 3 in solution, hypodermically.

12:06. Increased reflex to touch.

12:08. Reflex increased. Irritation produces sudden violent extension of extremities.

12:11. Animal quiet unless touched, when violent tetanic convulsion occurs, as in last experiment.

1:05. Spinal cord divided at about its middle. Reflex tetanic contractions persist below as well as above point of section. Lethal dose in this experiment 0.03 per kilogram.

Other experiments upon frogs were made with the same results.

From these experiments it is evident that the third alkaloid is much more powerful than either anhalonine or mescaline, and differs from them also in its physiological effects. Its lethal dose in frogs, guinea-pigs and rabbits is 0.02 to 0.03 per kilogram of body weight.

The most marked effect of the alkaloid is to increase the reflex excitability of the animal. This was produced by doses as small as 0.0136 per kilogram.

As the amount given was increased, this effect became more marked, and when large doses were administered violent reflex tetanic convulsions were produced. These effects were due to action through the spinal cord, as they persisted below the point of section, after the cord had been divided and the parts severed from connection with the brain.

The similarity in action between this alkaloid and strychnine is remarkable. Experiments were performed in which a frog was given alkaloid 3 and another at the same time strychnine, and the effects of the two drugs were compared. Almost no difference in effect whatever could be distinguished, the third alkaloid producing increased reflex excitability as surely and to as marked an extent as the strychnine.

The effect of chloral hydrate upon an animal to which the alkaloid had been administered is also of interest. To ascertain this, a lethal dose of alkaloid 3 was given to one frog, and to another the same dose of alkaloid 3, and in addition chloral hydrate in varying quantity in different experiments.

X.—3:40. Frog A, 0.03 per kilogram hydrochlorate of alkaloid 3 in solution, hypodermically.

Frog B, same, and in addition chloral hydrate, 1.00 per kilogram, in solution, hypodermically.

In frog A increased reflex excitability was noted in four minutes. The effect deepened into reflex convulsions upon irritation, as in experiments already reported, which continued until the death of the animal.

Frog B appeared normal at 3:45 and 4:00.

4:05. Extremities appear weak, and animal rests upon belly. By no stimulation can any increased reflex excitability be demonstrated.

4:07. Same. Stupid. No increased reflex. Condition remained same until death at 4:20, apparently from the effects of chloral. At no time did any increase in reflex excitability appear.

Other similar experiments were made in which, the dose of the third alkaloid remaining the same (0.03 per kilogram), the amount of chloral administered was progressively lowered. It was found that no increase in reflex excitability appeared until the amount of chloral was lowered nearly to 0.25 per kilogram. As the amount was still further lowered, reflex tetanic convulsions and the typical effects of the alkaloid appeared.

Furthermore, chloral appeared to act in frogs as an antidote in poisoning by the drug.

XI.—Frog; weight, three hundred and forty-four grams.

11:30. Injected lethal dose of hydrochlorate of alkaloid 3, 0.0103 in solution (0.03 per kilogram); also 0.086 of chloral hydrate (0.25 per kilogram).

11:37. Slight increase of reflex excitability to touch.

11:48. Same, more marked. Extension of legs on touch. Draws them up, however, and stands normally.

11:53. Tetanic convulsion on touch. Stupid. Rests on belly. Tries to hop occasionally. Draws legs up normally. Condition remained same for several hours and recovery upon following morning was complete.

XII.—In this experiment the same lethal dose (0.03 per kilogram) was injected, and but 0.125 of chloral hydrate per kilogram. Animal recovered.

In these experiments the amount of chloral given was insufficient entirely to counteract the effect of the alkaloid, but the animals recovered from what would otherwise have been a fatal dose of the third alkaloid.

From the results of these experiments we conclude that the most marked physiological effect of the third

alkaloid of mescal buttons is the production of increased reflex excitability, and, if the amount given be sufficiently large, reflex tetanic convulsions; this effect is produced by action through the spinal cord; chloral hydrate directly antagonizes this effect of the alkaloid, in small doses modifying the increase in reflex excitability, and in sufficiently large doses counteracting it entirely; and that the symptoms produced by the alkaloid in frogs, guinea-pigs, and rabbits appear to be identical with those produced by strychnine.

The action of the alkaloid upon the respiration and heart appeared to be entirely secondary to its effect upon the muscular system and the degree of involvement of the muscles of respiration. The breathing was absent during the tetanic convulsions and more rapid than normal during the interval of quiet, as was also the heart. No marked effect upon the pupil was found.

Other Constituents.—In addition to alkaloids, mescal buttons contain other ingredients, the most important of which is a resinous substance, which may be found to play an important part as the active principle of the drug. It is soluble in alcohol and ether, insoluble in water, and seems to be of a complex nature, as it can be separated into two or more portions by proper solvents. The buttons also contain other substances which possess more of chemical than of pharmacological interest. These include one or more wax-like bodies, and some of the carbohydrate constituents of the plant.

Therapeutic Uses.—The conditions in which it seems probable that the use of mescal buttons will produce beneficial results are the following: In general "nervousness," nervous headache, nervous irritative cough, abdominal pain due to colic or griping of the intestines, hysterical manifestations, and in other similar affections in which an antispasmodic is indicated; as a cerebral stimulant in neurasthenia and in depressed conditions of the mind—hypochondriasis, melancholia, and allied conditions; as a substitute for opium and chloral in conditions of great nervous irritability or restlessness, in active delirium and mania, and in insomnia caused by pain. In the last condition it acts to produce sleep not as a hypnotic, but by relieving the cause of the insomnia. In full physiological doses it produces insomnia, but in therapeutic doses it does not have this effect.

The following cases in which the drug was used may be mentioned briefly:

I.—Gentleman, aged fifty-five years. Chronic bronchitis with asthmatic attacks. Much distressed by an irritative cough which kept him from sleeping. A piece the size of a pea from the centre of a button was administered in the afternoon, to be dissolved slowly in the mouth. The irritative cough was speedily relieved. He took a second similar dose at bedtime and slept well through the night, which he had not done before for a long time. He returned to his home in New York and kept up the use of the drug with continued relief. In a letter received from him recently he states that he has improved very much, being able to sleep all night without rising, which he had not been able to do for two years; and that, although he has no need of it upon some days, he carries a piece of a button in his pocket constantly, as its use relieves the tickling in his throat at once and gives greater relief than any other remedy which he has ever used. It appears to have no curative effect—merely relieves the irritative cough.

II.—Gentleman, principal of high school, aged twenty-five years. Neurasthenia of six months' standing. The effect of the drug in this case seemed little less than marvellous. Three buttons were administered within an hour. This was followed by the characteristic color visions of the drug, and relief from

the bodily and mental fatigue with which he had suffered for six months, and he declared that he was "himself again, cheerful and happy." On the next day, and for several days thereafter, he continued to feel the beneficial effects of the drug. He has continued its use in dose of one-half a button when he feels it to be necessary. It invariably relieves the sense of bodily and mental fatigue.

III.—Lady, aged thirty-three years. Nervous prostration. The drug was administered in this case as in the last, but in smaller doses, with a marked beneficial effect. Mental and physical exhaustion were relieved and power to work was increased to a marked degree. There was no reaction.

IV.—Lady, aged forty-nine years. Chronic phthisis with facial neuralgia and catarrh of pharynx, larynx, and bronchi. The fluid extract of anhalonium was administered with beneficial effect. The irritative cough was relieved to a marked extent, the spells of coughing being less frequent and less violent and prolonged. Although she has been taking the drug but a comparatively short time, she has suffered much less than formerly from the facial neuralgia.

The following cases were reported by a gentleman of a Western State. The drug was administered under the supervision of his family physician:

V.—Gentleman, aged fifty-six years, large and strong physically. "Softening of the brain," onset dating back about a year. He was under the care of his two brothers who were physicians in Kansas, and was at times violent and required the constant attendance of a physician and two nurses. In an attack of violence, opium in the form of laudanum and morphine was given, commencing on Thursday, until the following Sunday, without beneficial effect. Upon Sunday at 2 P.M. he was given a teaspoonful of tincture of anhalonium. A teaspoonful was also given every half hour from 6 until 9 P.M. At 10:30 the patient went to sleep and awoke at seven o'clock, Monday, in rational condition. He felt so much improved that he left the next day for his home in Texas. The course of the original disease was not influenced by the drug, and he died a few months later.

VI.—Sister of above-mentioned gentleman reporting cases. "Very low and out of her head." One of the physicians above referred to used chloral to quiet her, and, this failing, administered tincture of anhalonium. It quieted her in a few minutes and she slept well and long. It seemed to be the turning-point in her illness, as she fully recovered.

The same gentleman reports that his wife formerly used to take the tincture for nervous headaches and that it always relieved her. She has them so seldom now that she does not use it.

The following preparations are suggested: Extractum anhalonii fluidum (one hundred per cent.). Dose, one-half to one gram (ten to fifteen drops).

Tinctura anhalonii (ten per cent.). Dose, four to eight grams (one to two teaspoonfuls).

Anhalonium (in form of buttons or powder). Dose, one-half to one gram (seven to fifteen grains).

The tincture should be made by the process prescribed in the United States Pharmacopœia for the preparation of tinctures. It should be of ten-per-cent. strength. The fluid extract should be made of one-hundred-per-cent. strength and in accordance with the method prescribed in the United States Pharmacopœia for the preparation of fluid extracts.

The taste of these liquid preparations is very bitter, but may be disguised by a suitable vehicle, such as a mixture of fluid extract of licorice and elixir of yerba santa.

In conclusion we would say that Anhalonium Lewinii (mescal buttons) must not be confounded with the intoxicating drink "mescal," used by the Mexicans and

others. This drink is the fermented juice of one or more of the species of agave.

1230 NINTH STREET, N. W.

TWO CASES OF "A RARE FATAL DISEASE OF INFANCY, WITH SYMMETRICAL CHANGES IN THE MACULA LUTEA" (KINGDON).¹

By CARL KOLLER, M.D.,

NEW YORK.

I wish to present to you two cases of a rare and generally fatal disease or degeneration in infancy, associated with early blindness and characteristic retinal changes. The credit for having first observed and accurately described such a case belongs to Waren Tay, who in 1881 presented the case before a meeting of the Ophthalmological Society of the United Kingdom. Tay's report of the case, admirable for its simplicity and completeness, reads as follows:

"Mrs. L—— brought her infant, aged twelve months, to the London Hospital, March 7, 1881. When the baby was a fortnight or three weeks old, it was noticed to have little power of holding its head up or moving its limbs. Since that time the weakness has become more and more pronounced. The mother brought the child to the hospital in the hope that something might be done to strengthen it. I could find nothing more than weakness, no absolute paralysis of any part. It seemed to me that its cerebral development was probably deficient, and I was induced to examine the eyes with the ophthalmoscope to ascertain whether there was any affection of the optic nerves. The mother had not suspected there was anything the matter with the sight, though when questioned closely she admitted she did not think the baby took as much notice as other babies. I found the optic discs apparently quite healthy, but in the region of the yellow spot in each eye there was a conspicuous, tolerably well-defined, large white patch, more or less circular in outline, and showing at its centre a brownish-red, nearly circular spot, contrasting strongly with the white patch surrounding it. This central spot did not look at all like a hemorrhage nor as if due to pigment, but seemed a gap in the white patch, through which one saw healthy structure. In fact, the appearances may most suitably be compared with those we are familiar with in cases of embolism of the central artery of the retina. I am quite unable to arrive at any conclusion as to the exact nature of the disease. I believe the changes to be situated in the retina, at any rate chiefly so. They may possibly be congenital. The family history throws no light on the possibilities of the case. This is the first child. There have been no miscarriages. There is no history of

phthisis in the family. The parents have been married two years and were not related before marriage. Dr. Hughlings Jackson kindly saw the child with me, and said there seemed no evidence of any definite cerebral affection. He could only say the baby seemed very weak. He agreed as to the local conditions present; so also did Mr. Hutchinson and others who have examined the child.—April 7, 1881.

"P.S. July 30th.—The baby has remained in much the same state as when first seen. There is still no definite sign of localized mischief, but the child lies almost helpless in its mother's arms. It is generally cheerful or else asleep; it is rarely cross. There is an important alteration in one respect, however; the discs are now undoubtedly becoming atrophic. The changes in the region of the macula are apparently precisely the same as before."

This child died at the age of one year and eight months. Two more cases of exactly the same kind occurred in this family and were described by Tay. Since Tay's first publication in 1881 a number of other cases have been brought to light by different observers—Magnus, Goldzieher, Knapp, Sachs, Wadsworth, Hirschberg, Kingdon, Carter—altogether nineteen (my own two cases included) that have been ophthalmoscopically examined and identified as belonging to the same group. To this list must be added a number of others that, according to the histories of the parents, have occurred in the same families and have closely resembled the cases examined, which brings the number of known cases up to something over twenty-five. Recently, Kingdon and B. Sachs, both of whom had the chance of observing a comparatively large number of the cases known, have collected and reviewed all the cases in literature. They are also the only ones who have made autopsies and microscopical examinations.

In reading through the histories of all the cases, one is struck by their uniformity. The children are born of healthy parents with no history of syphilis; most of them, if not all, are Eastern Jews, with their well-known tendency to neurotic degeneration. Up to the third or fifth month of age the children develop well; nothing unusual is noticed, unless a former case in the same family directs the attention to the ocular symptoms, which, in fact, seem to precede the others. Between the third and eighth month, sometimes sooner, a peculiar weakness of the muscles shows itself. The children are unable to hold the head up, the back is weak, the muscles are flabby, the reflexes are present. The further development is retrograde, both as to body and mind. The children do not learn to walk, present the picture of idiocy, and fall into a condition of marasmus, to which they succumb at the age of about two years.

The eye symptoms, although not always first noticed, seem to be the very first and seem to appear in the first weeks or months of the child's life. It is not likely that the retinal changes are congenital, as some observers assume. The ophthalmoscopic picture is of striking uniformity, and according to all observers very similar to the changes found in embolism of the central artery of the retina. The yellow-spot region is the site of a whitish opacity, the centre of which shows a cherry-red spot. The discs are mostly yellowish or grayish discolored, but otherwise appear normal and well defined; later on, atrophy develops. Pupils react sluggishly: in most cases, at least before the stage of complete atrophy, perception of light is present. In some cases there is oscillatory nystagmus.

The variations from this general picture are only slight. In many of the cases I find hyperacuity noted; in some of them convulsive seizures.

The affection is a family disease; two, three, and even four cases have been observed to occur in the

¹ Read before the American Ophthalmological Society at the Thirty-Second Annual Meeting, in New London, July 16, 1896.

same family. The nineteen cases reported and tabulated by Sachs occurred in ten families. All observers are agreed that syphilis plays no part in the etiology.

So far only three autopsies have been performed—two by Sachs of two children belonging to one family, and one by Kingdon. Both found changes in the layer of the large pyramidal cells in the cortex of the brain, and they interpret these changes as arrested development. Kingdon found descending degeneration in the cervical part of the cord. Sachs states expressly that no changes in any of the blood-vessels of the cortex were found. No satisfactory examination of the eyes has been obtained. Treacher Collins made sections of the eyes of Kingdon's patient, "but the result was unsatisfactory, as there was a fold of the retina in each eye at the macular region."

The history of my own cases is this:

Mary L—, then two years old, was brought to my dispensary service on June 18, 1894. The child had been born healthy and had developed well, until at the age of five months it was noticed that she did not use her eyes as other children of that age do. Nystagmus of the vibratory kind was present, which, according to the history, had developed in the first few months of the child's life. The ophthalmoscopic examination was very difficult on account of the nystagmus, and showed the discs in a congested state; besides, I find in my record the entry that apparently there was perception of light. There was nothing that struck me as unusual in the general condition of the child. The case was considered by me one of optic neuritis from an unknown cause. A second examination was intended, but the child was lost sight of until two years later, when an almost identical condition in an infant sister came under my observation, excited my interest, and led to the re-examination of the first child. She was now nearly four years old, but far behind others of that age in mental development. The latter had been retrogressive rather than progressive. At the age of one year she had been able to stand up, but she had never learned to walk. She was weak in her limbs and could not stand upright. At present she crawls and finds her way in the rooms of the institution (Montefiore Home for Chronic Invalids) into which she has been admitted. At the age of two years she had begun to speak a few words, but she forgot them. She knows her parents. She is very uncleanly in her habits, very irascible, and subject to fits of rage, in which she screams and scratches herself, unless she has her own way and is taken in the arms of her nurse, whereupon she becomes perfectly quiet. Altogether, she gives the impression of being an idiot. The condition of nutrition is very poor; several times it has seemed as if marasmus made quick progress and would soon terminate life, but with good care she has rallied again. Her muscles are weak and flabby; reflexes are present. There is hyperacuity and she starts at sudden noises. The eyes outwardly present nothing peculiar: occasionally there is a little nystagmus, but this is very much less marked than it was two years ago. The iris is bluish-gray; the pupils are of medium size; they have no prompt reaction, but become slowly narrower when exposed to light. After dilatation of the pupils with atropine the ophthalmoscopic examination is easy, the nystagmus being only occasional. The discs are sharply outlined, atrophic, yellowish discolored, and present the appearance found in cases of retinitis pigmentosa. The retina is atrophic. The choroidal vessels are visible, as in individuals having the same color of iris. In the region of the macula there is a slight, veil-like, milky-bluish haze, gradually fading into the color of the surrounding retina; in the centre of this opacity, at the site of the fovea centralis, is a

cherry-red patch, not very dark, a little smaller than the disc, with ill-defined outlines.

The second child, Hattie L—, was seen for the first time on January 8, 1896, at the age of two months. When the child was three or four weeks old, the mother, forewarned by the experience with the first child, noticed that it had nystagmus and did not seem to see. I found the eyes of normal external appearance, oscillatory nystagmus, and pupils of sluggish reaction. With the ophthalmoscope the media are found clear; the discs are sharply outlined, yellowish discolored, but otherwise appear normal. The retina exhibits the bright reflexes usually found in young individuals. The ophthalmoscopic examination is very difficult, on account of the strong nystagmus. Since the beginning of January I have examined the child six times, but have not found any unusual appearance of the fundus, except the yellowish coloring of the discs. In the left eye, however, there is at the site of the fovea a rather indistinct brownish patch; there is none of the white opacity in the yellow-spot region. The child begins to exhibit the signs of muscular weakness, and in every way, as the mother avers, behaves like her older sister.

The examination of the parents did not furnish anything of especial interest. They are both of the Jewish race and appear healthy; the mother is twenty-seven and one-half years old and the father twenty-six and one-half years. There is no history nor are there any symptoms of syphilis. Inquiry into their family history elicited nothing that could bear on the subject. They have been married six years. Ten months after marriage a boy was born, who is healthy. Nineteen months later a second child appeared, the girl that figures as my first case. During the seventh or eighth month of pregnancy with this child, the mother suffered a violent shock, her husband being brought home on a stretcher, on account of some sudden illness. Eighteen months after the birth of the second child, a third one was born—a girl, who is in good health. Eighteen months later the fourth child appeared, which is the second subject, as related above.

These two cases differ only in some minor points from the other cases described. As to the first child, which exhibits all the characteristic symptoms of the affection, she has reached the age of four years, whereas all the others died when about two years old. From the condition of the nutrition it appears very unlikely that the child can live much longer; in fact, her end has seemed near several times, but she has unexpectedly rallied each time. She has also reached a comparatively higher degree of development than the other subjects (being able to stand and to speak a few words), so that we may conclude that the affection in her case is of a milder form than in the others. In the younger child, although she has developed all the other symptoms of the affection, the characteristic retinal changes are missing, which proves that they are not congenital. In this connection it is remarkable that in Kingdon's second patient, who was seen at the age of three months (sister of a former patient) and in whom muscular weakness was just then beginning, the fundus oculi was normal. When the child was five months old a suspicious haze appeared at each macula; when she was eight months old the eyes exhibited the usual appearance.

It is to be hoped that this rare and interesting affection of the nervous system will be cleared up by pathological investigation with modern methods, especially with reference to possible changes in the vascular system. Until this has taken place, we can only state as our opinion that the anatomical substratum of the affection is most likely a degenerative process in the cortex of the brain and in the retina. From the clinical course of the disease, the original healthy condi-

tion of the children, and the consequent development of the marasmus and the characteristic changes in the eyes, we must conclude that we have to deal less with a condition of arrested development than with a progressive morbid process in the nervous system. The clinical picture of this affection in infancy is one that bears some resemblance to general paresis; general muscular debility without outspoken paralysis, physical and mental decay, and fatal issue being common to both.

THE DIAGNOSIS OF THE MORPHINE DISEASE.¹

By J. B. MATTISON, M.D.,

MEDICAL DIRECTOR, BROOKLYN HOME FOR HABITUÉS.

ON first thought, the title of this paper may seem somewhat trite; but a more sober second one will be likely to convince the reader that some cases of the morphine disease—disease, not "habit"—involve conditions so obscure as to make the diagnosis by no means easy; and the purpose of this paper is to present certain facts along somatic lines that will clear away doubt in suspected cases. There are morphinists who, so far as outward symptoms under ordinary conditions obtain, present no proof. Again and again, in my experience, this fact has been noted; and if this be so with one whose professional life is exclusively given to the study of this disease, it goes without saying that it is much more likely to occur with one engaged in general work, by whom minor evidence of this toxic condition might easily be overlooked.

I have known a doctor to take morphine fifteen years and present himself for treatment. He was cured and has been free six years, without showing the slightest sign of his drug disease. Of course, this was a very exceptional case, for usually the stamp of this neurosis is soon patent; but such a case is likely to reoccur and possibly involve such interests along medico-legal lines as to make a correct diagnosis of more than common importance.

This case in point: Nine years ago the wife of a medical man brought suit against him for divorce. He was charged with being a morphinic. The charge was denied, and a countercharge made that she was an *habitué*. This was denied, and, in proof of denial, she was examined by two physicians, who gave evidence that she was free from the disease. They were mistaken—she had been taking morphine daily for six years! They failed to make crucial test of her true condition, and so erred. She lost her suit, but, *en passant*, it may be said that the outcome was a happy one; for she came under medical care, recovered, was reconciled and reunited to the doctor, has since added to the census, and remained well.

Another case: In the appeal for a new trial for Carlyle Harris—who, you will recall, was killed for alleged murder of his wife with morphine—evidence was offered to prove that she was a morphinist, and so might have died from an overdose self-taken. The appeal was denied, and in his opinion, refusing, Recorder Smyth—the trial justice—laid special stress on his belief that had Mrs. Harris been an *habitué* the fact would have been known to her husband, in whose behalf on the trial no such claim had been made.

I have no hesitation in saying that in this part of his opinion Recorder Smyth made a grave judicial error. Why? Because many a case of morphinism in a wife has persisted for years unknown to her husband or even her doctor. That is a fact—just such a case of morphino-cocainism is now under my care; and, granting that the judge's belief along this line was the main reason for his refusal, if this fact had been properly presented and insisted on by competent counsel, it might have secured a new trial for Harris: which was, in my opinion—the claim as to the morphine being undecided—undoubtedly his due.

Many and varied as are the tokens of this toxic neurosis, it is safe to say there is not a single symptom infallible as a sign of the disease. This statement may be contrary to the general opinion in and out of the profession, but it is true. Anything like a "snapshot diagnosis" in morphinism may be quite unreliable, and should never be made. The usual various sequelæ—many of which may present in other disorders—are known to you, and details need not detain. The point of most value in this paper is a statement of the fact that we have at command two tests that are certain to detect chronic morphine taking. They are enforced abstinence and urinalysis.

Concerning the first, so imperative is the demand of the system for a sufficient supply of morphine at more or less regular intervals, when it becomes part and parcel of the daily need, that any withholding beyond a certain time is sure to be followed by symptoms that settle the narcotic status beyond doubt.

The length of this abstinence needful to determine the question varies according to temperament and condition; but as patients require the drug daily or usually more often, forty-eight hours' withdrawal will suffice for proof. Possibly, in some extraordinary case, a longer time may be needed; but, as a rule, two days will do.

Regarding the renal test, various methods will serve; but the simplest of which I know is that of Dr. E. H. Bartley, professor of toxicology in the Long Island College Hospital. This is the Bartley process: To the suspected urine add carbonate of sodium to make it alkaline. In this put a portion of chloroform; shake well, allow it to settle, draw off, and add a small amount of iodic acid. If morphine be present, a violet tinge appears.

With a consensus of symptoms usually noted, and the time and urine tests, the diagnosis of the morphine disease need never be long in doubt.

THE TREATMENT OF MEASLES WITH THE BLOOD SERUM OF CONVALESCENTS.

THE hope that the principles which govern the employment of antitoxin in the treatment of diphtheria could at once be applied to the treatment of other infectious diseases has not yet been realized. Conceding the correctness of these principles, it is obvious that they are capable of application only in the case of diseases whose etiology is determined and which are transmissible to lower animals. Among the diseases not yet placed in this category are a number common among children and of which more than one attack is uncommon in the same person, such as measles, scarlatina, and whooping-cough. In the case of these it is at present not possible to immunize lower animals and employ their blood serum in the treatment of the developed disease in human beings. On the other hand, it is possible to utilize for this purpose the blood serum of convalescents from the disease. The success of such treatment, it may be expected, will depend in a large measure upon the degree of immunity conferred by one attack of the disease. Measles may be included among the diseases in which this degree of immunity is considerable, and for this reason it furnishes a suitable example for the observation of any influence that may result from the therapeutic employment of the blood serum of convalescents. With these thoughts in mind, Weisbecker (*Zeitschrift für klinische Medizin*, vol. xxx., Nos. 3 and 4) has adopted this plan of treatment in a small series of cases in private practice. The first case occurred in a girl nine months old, who presented characteristic initial symptoms of measles without exanthem. An injection of ten grams of blood serum from a convalescent from the same disease was given. The catarrhal symptoms appeared for a day to be held in check, but they returned, and on the following day an eruption of peculiar character and distribution appeared. Large areas of cutaneous surface escaped, and the face was involved last. While no radical effect was observed, a certain favorable influence appeared evident. Upon the assumption that pneumonia occurs as a complication of measles when insufficient antitoxin is naturally developed to neutralize the circulating toxins, the serum was employed in four cases presenting this complication, with the happiest results. The children were one year, one and one-

quarter years, nine months, and five and one-half years old respectively, and received a single injection of serum varying from ten to eighteen grams. The cases were selected on account of their gravity; all terminated favorably and two by crisis.

THE BICYCLE FRIGHT.

THE extended use of the bicycle has brought to light numerous physical phenomena which have proved profitable subjects for speculation and study. Human ingenuity has been taxed to perfect the mechanism of the machine in almost every direction in which improvement is possible. Its weight has been reduced to the lowest standard consistent with strength and safety, the jolt is counteracted by cushioned wheels, the saddle has been constructed on anatomical principles, the friction has been lowered to the conservative maximum of effective power, while the entire apparatus has been so nicely balanced to the centre of gravity of the rider that the propelling power is as little embarrassed as is possible under the circumstances of ease and surety of progression. It is not so much the question of adaptability of the machine to the individual as of the individual to the machine. There is no doubt that a large number of the accidents for which the bicycle is so often blamed is more or less chargeable to the want of care and the lack of skill on the part of the rider. Particularly is this the case with many of the numerous collisions of which we hear so much. There is one peculiar cause of accident which appears to be particularly associated with the bicycle, in that the latter is in itself a special means to the end of producing a distinct and well-recognized form of nervous perturbation, which may, for convenience of description, be designated the bicycle fright. Although it occurs most frequently with inexperienced riders, it often attacks others who have under ordinary circumstances reasonable control of their wheels. Under certain conditions the passive machine becomes, by a mental perversity of the rider, an uncontrollable and active agent of an apparently unavoidable accident. The vehicle is thus forced to run into the very danger that the rider would otherwise avoid, and a direct collision is inevitable in spite of the frantic efforts to prevent it. So far from having any proper will force in the matter, the rider appears to aid the perverse and calamitous tendency. The phenomena are to be explained, however, on well-established psychological principles, and these differ in degree from similar ones in that they are more distinctly individual than under other and more usual methods of travel. It is purely and simply a perversion of determination on the part of the rider entirely uncontrolled by any other counteracting agency. The one element of safety for a frightened horseman is the possibility of there being some little remaining sense in the horse, some instinctive power on the part of the latter to avert collisions, independently of the demoralized occupant of the saddle. On the other hand, the runaway bicycle becomes an intensified exemplification of the rider's loss of individual control.

It would appear to resemble stage fright in many essential particulars. The intense and overwhelming desire to do well in the face of danger temporarily paralyzes the necessary will force and makes such a result impossible. The untrained bicyclist who wishes to avoid the vehicle approaching from an opposite direction finds himself helplessly steering toward the object instead of away from it. Under the hypnotic influence of concentrated attention, his movements become inco-ordinate, and in the struggle to regain his lost grip he becomes the hopeless victim of the perverted reflexes of purposeless effort and the abject subject of an optical illusion. When once attacked with this nervous malady it is almost useless to attempt to prevent its injurious tendencies. The victim can no more help himself than can the gnat resist the attraction of the flame. All attempts to collect the scattering wits usually add to the original difficulty and intensify the hysterical desperation of a lost cause. The only hope is in immediate dismounting and the gaining of an opportunity for the natural recovery of nervous equilibrium.

For obvious reasons associated with the well-known tendency to nervous disabilities in females, such phenomena are more frequent in that sex than in the other, but they occur often enough in both to demand serious attention in connection with the necessity for lessening the number of many avoidable accidents. So widely is this form of fright acknowledged, that teachers of bicycle riding lay special stress upon the danger of fixing the gaze upon any object necessary to be avoided, and in proof of their point frequently demonstrate to beginners the strange tendency, even in roomy halls, to collide with obstacles purposely placed in prominent positions. One of the remedies suggested is to look away from rather than toward the object to be avoided, fixing the gaze ahead and only in the direction in which the machine should be steered. On the same principle, it is uniformly advised that the rider should never look at the revolving wheel or the moving pedals.

THE HUNTER'S POINT STENCH AND THE STATE BOARD OF HEALTH.

THE Citizens' Organization of Brooklyn has made a formal complaint against the manufacturing nuisances at Hunter's Point, and the governor has very properly referred the matter to the State board of health for investigation and remedy. Similar protests have been made before by various parties individual and corporate, so that the reasons for the same are well understood by all who have been forced to give attention to the subject. The very name of Hunter's Point has become a designative synonym for offensiveness. No one has questioned the fact that the abominable stench that emanate from the regions of Newtown Creek are to the most extreme degree an outrageous nuisance, save the firms indirectly interested in the manufactories. The local and State boards have investigated the conditions for the production of these stench and have made elaborate reports, but nothing further has been done. Mean-

while, the inhabitants of the large adjoining districts of Brooklyn and New York continue to suffer from the sickening odors. Oftentimes when the wind is in a favorable direction for the transmission of the obnoxious vapors the windows and doors must be closed to prevent nausea, headache, and other evidences of vitiated atmospheric influences. Particularly is this the case in the dead of night, the intensity of the foul odor being sufficient to awaken the sleeper and deny him the commonest of all privileges, that of ordinary ventilation for his apartments. In view of the repeated failures to remedy this crying and defiantly persistent evil, it would naturally appear that either the State board of health has no power in the premises, or that it does not exercise it in the face of the strong political pull at the back of the interested manufacturers. We have so strongly suspected the latter element that we shall watch with becoming interest the conduct of the investigation about to be made. If the State board of health, boasting of its membership of independent and well-qualified men, desires to place itself on record as daring to tackle the question in the proper spirit, it will now have the opportunity to do so. It can soon prove which is the stronger, the rights of the people represented in the board in question, or the power behind that orders the pigeonholing of any perfunctory recommendation. At best we can only wait and see. There is no question concerning the necessity of abolishing the nuisance, but whether or not it can be done under the existing circumstances of dominant political influences is altogether another matter.

News of the Week.

Fire at Montpellier University.—A fire broke out on August 18th in the building of the Industrial Exhibition in Montpellier, France, which not only caused considerable injury to the exhibits, but also spread to the university buildings, the damage to the latter being estimated at 600,000 francs.

Norristown (Pa.) Hospital for the Insane.—Dr. Alice Bennett has resigned her position as chief resident physician in the department for women of the Norristown Hospital for the Insane, after a continuous service of sixteen years. The resignation has been accepted with regret by the trustees of the hospital and a committee has been appointed to select a successor.

Diagnosis of Glanders.—The health department of New York City is prepared to furnish mallein for the diagnosis of glanders in horses. This is prepared by Nocard's method, and is furnished in vials containing a single dose of 2.5 cubic centimetres. In order that accurate results may be obtained, the board has issued directions which those who use the mallein are advised to follow.

A New Journal.—Dr. José E. Calvo, of Panama, has established a journal to be published monthly, entitled *Revista Mensual de Medicina, Cirujía y Farmacia*.

Spanish Hospitals in Cuba.—Dr. Murata, a Japanese army surgeon, who was sent on a mission to Havana by his government, has described in a Tokio paper the condition of affairs which he found. He says the Spanish army surgeons are very far behind the times in their methods, and he describes the nursing as slovenly and negligent, the wounded soldiers being roughly treated by the surgeons and nurses. The latter appear to be laborers picked up in Havana and the neighboring country districts, very dirty and wholly ignorant of the first principles of care for the wounded.

American Academy of Railway Surgeons.—The third annual meeting of this society will be held in Chicago on September 23d, 24th, and 25th. Dr. John E. Owens, of Chicago, is president, and Dr. Webb J. Kelly, of Galion, O., secretary.

Vital Statistics of Philadelphia.—For the week ending August 15th there occurred in Philadelphia 838 deaths—348 more than during the preceding week and 280 more than during the corresponding week of last year. Of this number 315 (40 per cent.) were of children under five years of age. The largest number of deaths from a single cause—173 (20 per cent.)—was due to insolation. Other conspicuous causes, in the order of frequency, were as follows: Cholera infantum, 106; pulmonary tuberculosis, 50; heart disease, 40; marasmus, 34; gastro-enteritis, 31; senility, 28; inflammation of the brain and convulsions, each 27. There were reported during the week 65 cases of typhoid fever, 20 of diphtheria and 11 of scarlet fever. The number of deaths from these three diseases were 10, 8, and 1 respectively.

University of Pennsylvania.—Plans have been prepared and contracts awarded by the trustees of the University of Pennsylvania for the erection of a new building for the department of dentistry, to cost \$120,000. The exterior of the building will be of brick and terra cotta, with a tile roof, and the floors throughout will consist of slow-burning material. The structure will occupy a space one hundred and eighty by one hundred and thirty feet. On the second floor will be a large clinic hall, one hundred and eighty feet long by fifty feet wide, with excellent light from the north. There will be, besides laboratories of metallurgy and prosthetic technique in addition to the general and demonstration laboratories, a lecture-room for the accommodation of five hundred students, a large students' assembly room, toilet rooms, bicycle rooms, etc. It is expected that the new building, which will be heated by steam and lighted by electricity, will be ready for occupancy within a year.

The Tri-State Medical Society of Alabama, Georgia, and Tennessee will hold its eighth annual meeting in Chattanooga on October 13th, 14th, 15th. Dr. J. B. Murfree, of Murfreesboro, Tenn., is president, and Dr. Frank Trester Smith, of Chattanooga, secretary.

The Therapeutics of the Parks.—The president of the Kneipp-Verein, an association of believers in the cold-water maxims of Father Kneipp, recently addressed the park commissioners, asking permission to

walk barefoot on the lawns of the parks in this city during the early hours, while the dew is still on the grass. Next to wet compresses, this is regarded as one of the most efficacious of measures for promoting and maintaining health.

Gift to a Hospital.—Lord Mount-Stephen and Sir Donald A. Smith, the founders of the Royal Victoria Hospital in Montreal, have given an additional sum of \$800,000 for a permanent endowment sum. It is expected that the hospital will have an annual income of \$40,000.

Capture of a Hospital.—Colonel Molina, of the Spanish army, recently led an expedition against a hospital of the insurgents near Colon, in Cuba. Six of the Cuban inmates were killed and several of the attendants were wounded. The doughty colonel ought to be decorated for his victory.

Obituary Notes.—DR. ROBERT FLEET SPEIR, of Brooklyn, died at his home on August 13th, at the age of sixty years. He was a graduate of the University of Vermont in 1866. He was a brother of the late Dr. S. Fleet Speir.—DR. CURRAN C. SMITH, of Waco, near Richmond, Ky., dropped dead at his dinner table on August 13th. He was a graduate of the medical department of the University of Louisville in the class of 1850.—DR. JOSEPH AUGUSTUS MONELL, of New York, died at his home in this city on August 12th. He was born in 1826, and was graduated from the College of Physicians and Surgeons in 1850. He was a member of the New York County Medical Society, the New York Academy of Medicine, the New York Pathological Society, and the Physicians' Mutual Aid Society. His widow and a son survive him.—DR. WILLIAM WARING, of Upper Marlboro, Md., was stabbed to death on August 5th during a political quarrel.—DR. JONATHAN KAY PITNEY died at Absecon, N. J., on August 8th, at the age of fifty-nine years. He was a son of the late Dr. Jonathan K. Pitney.—DR. EMANUEL F. GERHARD died at Norristown, Pa., on August 13th, of typhoid fever, at the age of thirty-eight years. He was graduated from Jefferson Medical College in 1884 and at the time of his death was a member of the town council.—DR. HERMANN F. GULEKE, of this city, died on August 17th at Sheepshead Bay. He was born in Dorpat, Russia, in 1826, and studied medicine at Dorpat and Berlin, being graduated from the former university in 1854. Soon afterward he came to this country and was graduated from the New York Medical College. He was for many years visiting physician at the German Hospital.—PROFESSOR PAJOT died in Paris recently at the age of eighty years. He was for nearly forty years professor of obstetrics in the University of Paris.—SISTER MARY IRENE died in this city on August 14th. She was born in London in 1823, and became a Sister of Charity in 1850. In 1869 she established the Foundling Asylum in this city and brought it up from very small beginnings to its present prosperous condition. She was also instrumental in founding the Seton Hospital for Consumptives at Spuyten Duyvil.

There Were 1,091 Deaths from Cholera in Egypt during the week ending August 15th, bringing up the total number of deaths to 14,755.

A Loud Heart Murmur.—Dr. J. F. Baldwin, of Columbus, O., writes: "In your issue of May 9th is a report of a case of unusually loud heart murmur. Some three years ago I was consulted by a colored man, who, after a scuffle with a companion, had noticed a cooing sound in his chest. I found he had suddenly developed a mitral systolic murmur which sounded very much like the cooing of a dove. I could hear this distinctly when he was standing at the front door and I was at the extreme rear of my back office, a distance of about thirty-five feet. I passed the case around among my professional friends, and we tried to secure transmission of the sound by telephone, but it did not possess sufficient intensity to enable it to be heard. The patient complained of no inconvenience whatever, and the case passed from observation."

Against the Sale of Quack Remedies.—A new law against "unfair competition in trade," which has come recently into force in Germany, may, it is hoped, be taken advantage of to restrict the sale of nostrums. It is aimed against false descriptions and other forms of swindling by advertisements. Not only the advertiser, but the newspaper publishing the advertisement, may be prosecuted.

Wholesale Lead Poisoning.—The Rome correspondent of *The Lancet* relates a curious instance of widespread lead poisoning, especially in Milan, caused in an unusual way. It seems that the sausage manufacturers have to pay the usual tax on salted articles. As an evidence that this tax has been paid, every sausage is ticketed with a leaden seal. When so labelled the sausages are distributed to the dealers, and by the latter are sold to the public, in most cases already cooked, the heavy leaden seal still remaining attached. One may readily divine the consequences. Most sausages contain salts, such as nitrate of potassium, chloride of sodium, etc.; besides this, the intestine used as their envelope is washed with vinegar, or even moistened in wine, which also in turn becomes acidulated—all of them substances which in contact with oxide of lead produce poison of varying intensity. In this state the sausages are consumed by a large public, native and foreign, while the liquor in which they have been cooked—a liquor charged with the salts indicated—is distributed to the poor. It was only after analysis at the municipal laboratory of Milan that the extent of the mischief was realized. The manufacturers are memorializing the communal and civic authorities to replace the leaden seal by another made of some innocuous metal. Meanwhile, the origin of the unpleasant abdominal symptoms, of which there have been so many complaints recently, has now been discovered.

Women and Medical Societies.—A persistent effort has been made by the women physicians of London to gain the right of membership in the medical societies. After being repulsed by the Royal College of Physicians and Surgeons, they tried the Pathological Society, but with the same lack of success. The *Medical*

Press says that it had hoped the Pathological Society would rise superior to such petty professional jealousy and fear of successful rivalry; "but the sexual hyperæsthetics had it all their own way, and as they are impervious to reason and argument the ladies must e'en wait until these become too infirm to attend the meetings or until they are old enough to be superannuated. It is worthy of remark that fellows whose voices are never heard and whose forms are unknown under ordinary circumstances within these hallowed precincts, invariably turn up to defend the society which they profess to cherish, but which they never frequent, from the moral contamination involved by the presence on terms of scientific equality of the new order of practitioners. Science is asexual, and the relief of human suffering knows no distinction of persons. Women, as practitioners of medicine, labor under many inherent disadvantages, but this is not a sufficient reason for refusing to the more diligent and gifted among them free scope for their unemployed energies. Just as we naturally respect the man who has fought his way to the front in spite of opposition and difficulties, so we ought to regard the woman who, in spite of physiological burdens and social discouragement, has acquired the right to be enrolled a member of an honorable and humane profession."

Obituary.

JEROME COCHRAN, M.D.,

MONTGOMERY, ALA.

DR. JEROME COCHRAN, the dean of the medical profession in Alabama, died at his home in Montgomery on August 18th, of chronic nephritis. Dr. Cochran was born in Moscow, Tenn., December 4, 1831. He studied medicine first at the Botanic Medical College of Memphis, being graduated there in 1856. He began practice the following year in Fayette County, Miss., but went soon after to Nashville and took the regular course of lectures at the medical department of the University of Nashville, where he received the degree of M.D. in 1861. He then entered the Confederate army as surgeon, serving there for three years. After the war he settled in Mobile, where he built up a large practice. He was connected with the Medical College of Alabama for ten years, occupying first the chair of chemistry and later that of public hygiene and medical jurisprudence. Dr. Cochran was always identified with questions of public medicine and hygiene. He was the author of the medical and health laws of Alabama, was health officer of the State and chairman of the State board of medical examiners and of the committee of public health of Alabama. He was a recognized authority on yellow fever, having been a member of the yellow-fever commission in 1878, and being also the author of many articles on that disease in American and foreign journals and systems of medicine. He was a member of the American Public Health Association and of many other societies. At the Atlanta meeting of the American Medical Association he was chosen to deliver the address on State medicine at the semi-centennial meeting in Philadelphia next year. He was an advocate of the establishment of a national health bureau, but thought this object could be attained better by enlarging the duties and powers of the Marine Hospital service than by creating a new organization. He leaves a widow and two sons.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Sixty-Fourth Annual Meeting, Held at Carlisle, July 28, 29, 30, and 31, 1896.

(Continued from page 244.)

SECTION ON MEDICINE.

Second Day—Thursday, July 30th.

Discussion on Anæmia.—DR. F. TAYLOR opened the discussion. Anæmia may be defined in general terms as an abnormal pallor of the tissues, a definition that means a good deal more than it says. It may be broadly divided into primary and secondary, the first being that form of anæmia that arises spontaneously without any definite cause, while the second follows such debilitating diseases as cancer.

The first or primary form is named also chlorosis, and is eminently a disease of the young; another primary form is called, not very happily, pernicious anæmia, and may occur at any age.

Chlorosis is also known by the name of idiopathic anæmia and is usually associated with constipation of the bowels, while diarrhœa frequently complicates pernicious anæmia, which is also more likely than chlorosis to be accompanied by various hemorrhages. In pernicious anæmia there is often the association of fatty degeneration of the heart.

Chlorosis is sometimes complicated by gastric ulcer, the formation of ptomaines in the stomach and intestines, and occurs in women from the age of puberty to about twenty-two years, though instances are recorded of chlorosis setting in at a later age, even at forty-one years in one case; and, as a rule, it is an affection from which the patient after a time recovers.

The speaker has noticed in chlorotic females a decided preference for green colors and an objection to anything pink or red. The cause of an attack is not apparent; but as it is ascertained that in females the specific gravity of the blood falls at the commencement of puberty, while that of the male rises at the same period of life, it may be that some hæmostatic correlation exists between the lowered gravity of the blood and the disease. Iron is the accepted remedy in chlorosis, but, the lecturer thought, is usually exhibited in too small doses.

The degree of anæmia does not always correspond in the young with the amount of food taken, for in some cases the nutrition of the patient does not appear to be interfered with.

Chlorosis very seldom indeed had a fatal termination. Pernicious anæmia might be primary and progressive, and was often rapidly fatal; following a drainage of the system from bleeding piles, pregnancy, etc., and sometimes supervening after a single attack of hemorrhage. In pernicious anæmia there was a great diminution of the blood corpuscles, and at the same time an increase of hæmoglobin in the individual corpuscles. Affections of the spleen might produce anæmia, and not infrequently would be found to be associated with syphilis.

The great point in the treatment of chlorosis was perfect rest, and without it iron would often be found to be productive of very little good; fresh air had a beneficial effect, but exercise should be regulated by circumstances, and might be injurious, especially if there were any cardiac complications. In the treatment of pernicious anæmia the sheet anchor of the physician was arsenic; of late stress had been laid upon the successful exhibition of extract of bone marrow, the action of which had not been hitherto explained satisfactorily, but it appeared to arrest the

destruction of the blood corpuscles. How? Well, as the Devonport brothers said, "We don't know how we do it, but we do it!"

The inhalation of oxygen had been tried, but without much benefit. Iodide of potassium occasionally acted like a charm, but in such instances the speaker was of opinion that there was, undoubtedly, a syphilitic taint, for in other cases in which it was known that there was none it was inoperative.

In splenetic anæmia great benefit had resulted from splenectomy, but the operation was a heroic one, not to be lightly undertaken.

DR. BRYON BRAMWELL announced his intention of referring mainly to the treatment of anæmia, chlorotic and pernicious, although there was a great difference between the two, for in the former it was the number rather than the composition of the blood corpuscles that was affected, while the very contrary obtained in the latter. Chlorosis might exist without constipation and the remedy was iron—Blaud's pills in large doses. The speaker had given as many as forty-eight of these on the fourth day, and continued them for three or four weeks. It was necessary to keep the patient in bed in a large airy room, and that was the reason hospital patients were more apt to recover quickly than private ones.

More than one condition was included under the term pernicious anæmia; in one form a great deal of iron would be found in the liver, owing to the rapid destruction of the blood corpuscles that was going on, and in others there was rather an imperfect formation of them, and consequently little or no iron was to be met with in the liver or in the portal system. The sequel of a long-continued drain, as from the uterus, was identical with idiopathic pernicious anæmia, and the early exhibition of arsenic was advisable; it was also desirable to continue it for some time after recovery, as relapses were of frequent occurrence. Anæmia was often found to be coexistent with the presence of worms in the intestinal tract.

DR. J. M. CLARK thought it was important to diagnose early between chlorosis and pernicious anæmia, as the latter was often complicated by, if it did not actually result from, syphilis, and in these cases iodide of potassium was of extreme value. He had found permanent benefit to result from the inhalation of oxygen.

DR. W. T. GAIRDNER, of Glasgow, had not found the antiseptic treatment of anæmia in the least satisfactory, but the administration of arsenic was followed by the best results, whether there was imperfect formation or undue destruction of the blood corpuscles. The speaker cited cases that had come under his own observation.

DR. AFFLECK thought that in some cases there was a natural tendency to get well, and in others to get worse, independently of treatment. In chlorosis he advocated rest, and held that the influence of sunshine was of paramount importance. They had none too much of this precious commodity in Scotland, but what they had was utilized to the utmost; the ward in which anæmic patients were placed was in the warmest quarter and the sufferers were made to bask in the sun on the balcony with immense advantage. He thought heroic doses of iron were unnecessary, a far smaller quantity being required than had been mentioned by some of the speakers. Pernicious anæmia was a specific disease, and in the treatment of it he gave a decided preference to arsenic over bone marrow, which he had, moreover, found patients were extremely unwilling to take, while none objected to a few minims of the arsenical solution, and that was by no means an unimportant consideration.

DR. HANDFORD also advocated rest, but thought that it acted differently in the case of private and hospital patients, for it was nothing new to the former, but was of benefit to the latter, who knew but little

about it. He had met with a severe case of pernicious anæmia in a lad of sixteen, in whom the administration of arsenic produced a temporary improvement; when the patient stopped taking it he had a relapse, and this occurred several times, but ultimately he recovered, and was then a strong and healthy laborer.

Splenetic anæmia differed from leucocythæmia, and arsenic was more beneficial than bone marrow. He usually gave from ten to fifteen minims of the arsenical solution, but there were cases in which it could not be taken; it all depended on the idiosyncrasy of the patient. When arsenic could not be taken, bone marrow was useful. Stress had been laid upon the benefit to be derived from sunshine, but in Stuttgart chlorosis was endemic, although that city was situated in a warm sheltered valley where the sun exerted its power to an extent inconceivable by the denizens of the more sombre British islands; the sanitary condition of the sunny valley, however, was deplorable.

DR. ALEXANDER CRAIG thought that chlorosis and pernicious anæmia were caused by the presence of uric acid in the blood; if the uric acid were eliminated the anæmia would cease. Uric acid could not only be eliminated from the system, but its formation could be prevented by attention to diet. The speaker offered to let any one examine his blood, but no one having volunteered to do so, he concluded his remarks by stating that it was then quite normal. One or two other gentlemen having said ditto to those who had already spoken, and time pressing, DR. TAYLOR replied briefly, and the business of the section was then suspended to enable the members to witness some demonstrations in another part of the building. The session having been resumed after an interval, DRs. DRUMMOND and MORISON, of Newcastle, read a paper on "Ascites Due to Cirrhosis of the Liver Cured (?) by Operation," but when the patient was produced some of those present did not seem to think he was by any means saved.

DR. ALLISON, of Newcastle, then read a paper on "Deformity Treated by Bone Marrow," and showed cases, casts, and photographs, which were of considerable interest.

DRs. SAMUEL WEST and BRADBURY read papers on "Uranium Nitrate in Diabetes" and expressed themselves satisfied with the results, though the drug appeared to others to be, as yet, upon its trial.

DR. JOHN WALLACE read a paper on "Exploratory Incision Versus Paracentesis in Ascites," which gave rise to some unimportant discussion.

DR. WILLIAMSON read a paper on the "Clinical Diagnosis of Diabetic Blood" and DR. ROBERTSON one on "Diabetes Insipidus Cured by Electrization of the Medulla Oblongata."

DR. SAVILL produced an essay on the "Pathology of Itching and its Treatment by Large Doses of Calcium Chloride."

DR. BOKENHAM brought forward "Statistics of Orthotherapy of Diphtheria" and DR. AITKEN read a paper on "Raynaud's Disease Associated with Uremia," which brought the list of papers submitted for this day to a close.

Third Day—Friday, July 31st.

Discussion on Tuberculosis.—DR. J. W. MOORE, of Dublin, opened the discussion on this subject. He began by alluding to Koch's cure, which came in on a wave of enthusiasm and went out after a brief period of trial on one of despair, and tuberculosis still reigned in the midst of us, affecting not only man himself but the animals on which he depended for food. It was at one time held that heredity accounted for fully forty per cent. of all cases of tuberculosis, but that was a position that had to be abandoned. Heredity certainly had an influence on the disease, but it was a

limited one, for it is the tendency to the disease that is inherited and not, as in the case of hereditary syphilis, the actual disease itself. With regard to the infectibility of tuberculosis, there is and can be no doubt that it is essentially of an infectious character, but without the presence of the bacillus that gives rise to it there is no tuberculosis. Stamp out the bacillus and you get rid of the disease. It is most important to recognize the early signs of the disease, but these are not of an unequivocal nature; for instance, the red line along the gums may be due to other causes, as may also be the clubbed finger tips and ridged nails, which are common to other diseases resulting from malnutrition. The same may be said of morning-sickness and distaste for food, which are also characteristic of the early stage of pregnancy; but there is tenderness on pressure over the apex of an affected lung, less movement of the chest walls than is natural, and an intensity of the heart sounds in the same region. The damage done by tuberculosis is practically incalculable, and its ravages are greater in Ireland than in Scotland, and especially more so than in England and Wales.

Existing causes are the malign influence of town life, dusty occupations, and such as have a tendency to lower the vitality of those who are engaged in them. The favorite site of tuberculosis is in the lung tissue (pulmonary phthisis), but it also attacks the brain membranes (meningitis), the glands (scrofula), etc. Not many years ago tuberculosis caused nearly twice as many deaths in Brussels as all the zymotic diseases put together, but owing to improved sanitation of recent date the mortality had materially declined.

In order successfully to repel the attack it is necessary to carefully study the manner in which it is carried out. The doctor instanced the case of a poor man suffering from tuberculosis in an early stage, and who was not particular as to where he let fall his expectoration, and a child previously healthy became infected through crawling about the floor. There was no fear of infection being conveyed by the breath, but kissing consumptives on the mouth was much to be deprecated. While in a moist state the sputum was practically innocuous so far as non-contact was concerned, but when it had dried and become pulverized it was the source of infection, for the dust was liable to fall on food and into water and was thus conveyed into other systems. Milk in its raw state was a frequent source of infection, and extraordinary precautions were taken in Denmark to render it harmless by cooking. Sunlight was one of the most reliable disinfectants; the bacillus could not long survive exposure to the genial rays of the sun. Deep inhalations of free air were of the utmost importance. The speaker deprecated the habit of spitting into handkerchiefs, but if these were used they should be at once disinfected by plunging them into a four-per-cent. solution of carbolic acid. Japanese paper should be used and could be immediately burned. *Delenda sunt sputa!* They must be destroyed at any cost. The too familiar "dusting" was to be highly deprecated; a damp cloth should be used, and that should also be disinfected. The foolish, almost insane, dread of night air that prevailed so generally must be combated and shown to be groundless. What was wanted was pure air (avoiding draughts), nourishment, punctuality in meals, and no stimulants. General hospitals were unsuitable for the treatment of tuberculous cases, for which special institutions ought to be provided, and these should be classified so as to have one place for the commencing case and one for those whose recovery was hopeless—the Friedenheim (peace house) of the Germans. However, where such could not be provided, special wards for consumptive patients should be set apart in the general hospitals. With regard to long sea voyages and residence at mar-

itime resorts, the speaker gave the preference to the former, but thought it was cruel to send a patient hopelessly ill away to die among strangers. A patient once told him that "sea air" was too strong for him, and the speaker thought there was something in that. Mountain resorts had their advantages, but he advised stoppages *en route*. He had heard that the climate of Tasmania was favorable, and instanced the case of a lady whose friends thought she would die on the voyage, who completely recovered there and remained well at the age of sixty-six. A high temperature did not by any means, the speaker thought, debar a patient from the use of animal food, if he cared to take it and had any appetite. Milk was very good but required to be sterilized, and kumyss had its advantages, as also had maltine; cod-liver oil, of course, was valuable, especially when combined with saccharated solution of lime. Chloride of calcium was invaluable in cases of hæmoptysis, the attacks of which were much diminished by its use. Quinine made an admirable mouth and throat wash. Cough was relieved in a most remarkable manner by the inhalation of oxygen, and extract of condurango had a marked effect in dyspepsia. Salol, guaiacol, and iodoform were useful when there was diarrhoea, and small doses of cocaine were of much benefit in vomiting. At one time mercury was freely employed in the treatment of tuberculosis, but it had fallen out of repute. With regard to the question of notifying tuberculosis as an infectious disease, the speaker thought it would not be desirable, the difficulty being where to draw the line; but he was strongly of opinion that every case of death from tuberculosis should be notified as such, and that the room in which the patient had been lying, perhaps for months, should be thoroughly disinfected.

DR. HAVILLAND HALL agreed generally with what Dr. Moore had said in his very exhaustive paper, and especially with regard to the inadvisability of treating consumptive patients in general hospitals, except in cases of acute laryngeal phthisis, which derived so much benefit from the ablation of tonsils and laryngeal growths. It was a good plan to put a five-per-cent. solution of carbolic acid into the spittoon, and to use handkerchiefs of Japanese paper, which might be immediately burnt; but he deprecated spitting into the fire, as grates had to be cleaned and spitters occasionally spit wide of the mark. The necessity of free ventilation and sunshine went without saying, but there was no ideal climate for consumptives; there was some drawback everywhere, and better results would, on the whole, be obtained if they stayed at home. He particularly warned them against going to South Africa—any part of it—particularly if there was any digestive trouble. The question of temperature was not an important one, but if anything a cold climate was better for young subjects, and a warmer, milder one for those who were more advanced in years. He did not consider sea voyages desirable, as the miserable accommodation did more harm than the air did good. Great care must be taken not to upset the digestion by prolonged treatment with guaiacol or creosote, but the carbonates of those drugs given in milk or coffee were admirable. Salicylate of bismuth was most useful in the treatment of diarrhoea.

DR. SHINGLETON SMITH was affected with tuberculosis when he was young, but was cured by a long sea voyage. He thought it was possible to attack the bacillus in its stronghold and destroy it there. If guaiacol disagreed when taken by the mouth, it could be injected hypodermically. He had used guaiacol to the extent of from sixty to ninety minims daily, until the patient fairly reeked with it. Creosote was well borne in the early stages of the disease, but less so afterward. He thought that tuberculin had been taken up rashly and abandoned as rashly.

DR. GRIMSHAW, referring to the supposed influence of heredity, was of opinion that the members of a family took the complaint from each other. He advocated large windows so as to admit plenty of light. He did not think that notification of tuberculosis was practicable except when death had resulted, when the true cause should certainly be given.

DR. AFFLECK believed in personal infection and thought that if a person afflicted with tuberculosis was admitted into a general hospital he should be strictly isolated. He also agreed with the suggestion that there should be separate institutions for patients in the initial and in the advanced stages of the disease, for it was horribly cruel, he thought, to expose even a person suffering from one incurable disease to the risk of contracting another.

DR. PHILLIP thought it was not wise, as Dr. Moore had done, to allow tuberculous patients to expectorate into the fire, or rather into the fireplace. He thought the influence of change of air on the type of the disease had scarcely been realized. Patients should be instructed as to the value of fresh air and of fresh water in the shape of a daily bath. He found that breathing night air had a wonderful effect in stopping cough and night sweats, in improving the circulation and the digestion. With regard to specific treatment, the foe must be met, and the system saturated with remedies—carbonates of guaiacol and creosote. True, these were expensive drugs, but they might be used subcutaneously. Inunctions, too, of guaiacol and cod-liver oil were very valuable. He advocated placing hospitals for tuberculosis in busy centres and not in the country, as Drs. Moore and Grimshaw had done. It was a duty to provide dying-homes for the poor incurables; but the great fault of the system is that men are not taught to diagnose.

DR. FREW said the question was not only how to bring the bacillus into position, but how to prevent others from coming in. He thought climate had much influence in these cases, and mentioned the west coast of Scotland as a favorable place to send consumptive patients to. His own experience with hypodermic injections had been unfortunate, but he would give the plan a further trial. He quite believed that guaiacol neutralized the toxin, and thought the recovery of any patient ought not to be considered hopeless. Patients often derived great benefit from their stay in hospitals but relapsed as soon as they were sent back to their wretched homes.

DR. BEZLEY THORNE said he was not an authority on tuberculosis, but he questioned whether creosote reached the lungs when given by the mouth; he thought it did not, and suggested that its action was that of a gastro-intestinal disinfectant. He instanced cases of subcutaneous injection of guaiacol (his own among the number) that had gone back when the mode of administering the drug was changed, but improved again as soon as the injections were resumed. He was struck with the overwhelming gravity of the mortality in Great Britain from the various forms of tuberculosis. A man was not admitted into a hospital until his case was practically hopeless; there was no provision for the treatment of the disease; such matters were managed much better abroad.

DR. ODELL thought it might be considered presumptuous on the part of a mere general medical practitioner to give his opinion after the learned professors who had spoken, but he thought there were places in England to which consumptive people could be sent with advantage—Torquay, for instance, where they had separate hospitals for the curable and for the incurable. The rich could go where they liked, and the poor, as a rule, were taken care of; it was the poor gentlefolk who suffered most. He fully appreciated the value of the outdoor treatment of the disease and

thought that the Koch treatment had been too quickly abandoned.

DR. VAN SOMEREN was of opinion that the condition of life was of more importance than change of climate: if the former was not good, the latter would produce little benefit. It was all very well to express opinions, they ought to be put into practice.

DR. COLIN CAMPBELL thought they tried every means of getting at the bacillus except the direct one, and yet it was perfectly easy to put thirty grains of guaiacol into the lung; it should be mixed with glycerin and the syringe used should be long enough to reach below the vocal cord. He had used this mode of treatment in over two hundred and fifty cases, and even in some cases in which there were cavities in both lungs, great benefit had resulted. His advice was "to go direct for the bacillus."

DR. BRÖNNER had used menthol with remarkable results, but thought the operation was not such an easy one as the last speaker wanted to make out. He used the menthol combined with olive oil. He considered the tuberculin treatment unfortunate.

DR. MOORE in reply said he did not think the bacillus could be reached directly in its stronghold, where it was entrenched behind a triple line of defences, for it was only too well able to take care of itself. He thoroughly endorsed all that had been said about free ablutions and believed there was a glorious future in store for orrhoterapy.

DR. GRIMSHAW moved the following resolution: "That the government be approached by the association to urge the infectious nature of tuberculosis and the necessity for treating it in a separate place."

DR. GAIRDNER seconded and said that he was not one of those who advocated treating all tuberculous patients as if they were lepers; but the disease haunted certain sites, as typhus had done and did, and he thought it was no one's place to build houses for the classes who willed to live like pigs; until the towns were rendered unliveable for them there would be no improvement.

The resolution was carried unanimously. MR. OWEN read a paper on "Thymus Feeding in Exophthalmic Goitre."

Cerebro-Spinal Fever.—DR. FREW read a paper on "Cerebro-Spinal Fever in Scotland," which he said was frequently confounded with typhoid, but admitted that the differentiation of the two complaints was difficult. It was also confounded with tuberculous meningitis and with influenza. He had seen recoveries, but death often supervened rapidly. A short but unimportant discussion followed, and the meeting came to a close.

SECTION ON OBSTETRIC MEDICINE AND GYNECOLOGY.

First Day—Wednesday, July 29th.

Address of the Chairman.—DR. HALLIDAY CROOM, of Edinburgh, delivered a short introductory address, in which he drew attention to the brilliant advances made in gynecology of late years, and said that, having raised ovariectomy to a high pitch of excellence, surgeons were now turning their attention to the treatment of uterine cancer. It was estimated that there were eight thousand women in England and Wales alone suffering from cancer, and that of all women who died of cancer, in at least one-third of the number it attacked the pelvic organs.

He viewed with scepticism some of the statistics published by German surgeons, showing operations in a large percentage of cases of cancer of the uterus with such satisfactory remote results, as he found that in very few of the cases which he saw was an operation for complete removal admissible. In order that a

radical operation may be undertaken, it is essential that the uterus should be free and that the cervix can be drawn to the vulva.

Statistics show that we may expect a duration of life of about two years without operation, so that unless the operation promises a longer period than this it is useless. He deprecated all partial operations. The mortality of hysterectomy was not great. In his own experience he had met with three hundred cases, and but very few of these were suitable for operation. Patients nearly always applied too late, and in this relation the responsibility of the physician to recognize early was great, as he believed that with early recognition and vaginal hysterectomy one should get as good results as in cancer of the breast.

Senile endometritis and cervical inflammation and catarrh caused symptoms which most resembled those of cancer.

As regarded vaginal hysterectomy for other cases, such as prolapse and fibroids, he thought it bid fair to be overdone, as neither of these diseases were necessarily fatal. He thought that it was needed sometimes for small fibroids and for persistent uterine hemorrhage which could not be checked by other means. He would not advise vaginal hysterectomy for puerperal septic conditions, as had been done in America. The only post-partum condition for which he would do it would be the rare disease known as deciduoma malignum. In chronic inflammatory diseases of the uterus and appendages, vaginal hysterectomy offered advantages over abdominal section, as the drainage was complete and there was no danger of hernia. Vaginal hysterectomy for fibroid was now being supplanted by complete removal by combined abdominal and vaginal incision, "pan-hysterectomy," and this might be done when oöphorectomy had been tried and had failed. Oöphorectomy had been done for some general diseases with good effect, notably for osteomalacia, and some cases had lately been recorded in which the removal of the appendages had been said to arrest the growth of mammary cancer.

Discussion on Dysmenorrhœa.—DR. MURDOCH CAMERON, of Glasgow, opened the discussion. He thought the spasmodic form was the most common, and he advised dilatation with solid graduated dilators. He never used tents; he always passed a sound first, then seized the cervix with volsella, with sound *in situ*, as by doing this there was no risk of including the cervical canal in the grasp of the volsella. He followed this up by the occasional use of a white-metal stem pessary in the intermenstrual periods.

DR. CHRISTOPHER MARTIN, of Birmingham, said that it was important to make perfectly certain of diagnosis, as salpingitis might be overlooked and dilatation done, with disastrous consequences. He would divide the causes into intra- and extra-uterine, and of the latter the most common were inflammation of the tubes and chronic peritonitis; and he would distinguish the factors of spasm, congestion, and neuralgia. He would treat by rest, hot douches, and glycerin plug, and, as regards drugs, would especially avoid alcohol and opium. He used suppositories of the extracts of belladonna and cannabis indica, one-half grain each. In the neuralgic form he gave antipyrin. In other cases, potassium bromide, belladonna, and viburnum prunifolium. He found that dilatation gave only temporary relief. He had tried conservative operations, consisting in opening the abdomen, freeing adhesions, treating small cysts of ovary by ignipuncture, and fixing the uterus to the abdominal wall when he found it prolapsed. With oöphorectomy as a last resource, in one or two cases he had removed the uterus by vaginal hysterectomy.

DR. INGLIS PARSONS, of London, would advise examination under chloroform of unmarried women, as

it was impossible to make a satisfactory diagnosis otherwise. He did not believe in the ovarian origin of dysmenorrhœa, and instanced cases of large ovarian tumors in which no dysmenorrhœa had occurred. He considered antelexion a cause, and treated it by dilators. He thought that the pain was due to obstruction caused by the antelexion, and found that the size of the uterus increased during menstruation.

DR. J. D. WILLIAMS, of Cardiff, thought that there was one class of cases in which the women, if married, were sterile; and in these no inflammatory lesion could be detected, but the uterus was small, antelexed, and excessively mobile. He believed that it would be found that a diseased condition of the mucous membrane near the internal os was present, and that uterine contractions took place during menstruation. He had found benefit to be derived from nitrite of sodium and diffusible stimulants. He had found an intra-uterine stem pessary to do no good and dilatation often to fail.

DR. AMAND ROUTH, of London, pointed out that dysmenorrhœa was only a symptom, and thought that most cases were of the spasmodic variety. There was too much done now in the way of mechanical treatment. Most girls with dysmenorrhœa were constipated and anæmic, and both these conditions should be treated. He had found phenacetin in ten-grain doses every three or four hours to give relief, and also found good to result from antipyrin and from nitroglycerin in one-drop doses of one-per-cent. solution. The organs could be well examined per rectum, and he did not think it was necessary to give an anæsthetic for examination purposes. In those cases of dysmenorrhœa in which the pain preceded the flow, a glycerin tampon gave relief by removing the congestion.

DR. LYCETT, of Wolverhampton, pointed out that the rheumatic and scrofulous diatheses should be recognized as causes.

DR. BEDFORD FENWICK, of London, thought most cases were due to congestion. This might be relieved by aperients, scarification of the cervix, and glycerin tampon. Many cases were due to rheumatism, and in these potassium iodide did good. Dilatation was in his opinion both unscientific and unsatisfactory, and if anything were done to widen the cervix it should be the removal of a good piece of the anterior lip.

DR. BYERS, of Belfast, remarked on the extraordinary difference of opinion shown. He thought that many cases had their origin in the nervous system. He was opposed to stem pessaries. He did not think antelexion a cause, as it was often present in a marked form without causing dysmenorrhœa. He had found cycling to do good in some cases.

DR. PARSLow, of Birmingham, had found many cases in which there was no pain during the first three or four years of menstrual life, and then pain began. These cases could not be due to any congenital malformation, and he thought they were neurotic. He thought it very unwise to make vaginal examinations or treat mechanically unless good was likely to be done, as it was most unfortunate for a young unmarried girl to get the idea that there was "something wrong with her womb."

MISS KETTLE, of Edinburgh, had also found many cases in which the pain had not commenced at puberty, and had found that the first attack frequently originated from some slight cause, as catching cold during menstruation, overexertion, or other imprudence; and in these cases the pain might last for a few periods and then disappear. In the unmarried she would not make an examination until she had tried treatment for at least three months, and she would avoid directing a girl's attention to her uterus.

DR. CAMERON, in closing the discussion, said that he thought that there was one prevalent cause which

had not been mentioned, and that was the artificial avoidance of conception.

Hysterectomy for Fibroids.—DR. A. DONALD, of Manchester, then read a paper on "Intraperitoneal Hysterectomy and Total Hysterectomy by the Combined Method, for Fibroid Tumors of the Uterus, with a Series of Cases." He considered the whole question and gave the preference to the latter operation, tying the broad ligaments in sections and bringing the sutures down through the vagina.

DR. MARTIN, of Birmingham, in discussing this paper, said that formerly he left all ligatures long and drew them down into the vagina, but now he cut off the upper ones and brought down only the lower one.

Electricity in the Treatment of Uterine Neoplasms.—DR. HERBERT WHITE read a paper on "Practical Observations on the Electric Treatment of Uterine, Mammary, and Other Growths." He used a constant current of about seventy milliamperes and punctured the growth with the negative needle. He showed photographs illustrating the good results, particularly in a case of rodent ulcer.

DR. INGLIS PARSONS said he had used currents of three hundred milliamperes in the same way, using two platinum needles, fixing the negative one and using the positive as a pencil over the surface of the ulcer.

Prevention of Tetanus of the New-Born.—DR. G. A. TURNER, of Glasgow, read a paper on "The Successful Preventive Treatment of the Scourge of St. Kilda—Tetanus Neonatorum." He gave an interesting account of the island of St. Kilda, which lies west of the Hebrides and is rarely visited from the mainland. For the past one hundred and fifty years as many as sixty-seven per cent. of the children had died from this disease, the symptoms commencing with rigidity of the jaw on the fifth or sixth day and the child dying on the eighth day. Various theories had been brought forward to account for this, some attributing it to the excess of fat in the mothers' food, others to the insanitary, ill-ventilated dwellings. Dr. Turner's advice was requested by the clergyman of the island. He came to the conclusion that the germ must enter through the stump of the umbilical cord. He advised treating the cord antiseptically with iodoform and gauze, and strict attention to cleanliness of the child; and these measures had proved so efficacious that there had been no case in the last two years.

Second Day—Thursday, July 30th.

The Causation and Treatment of Secondary Puerperal Hemorrhage.

—DR. AMAND ROUTH, of London, in opening the discussion on this subject, said that he would define secondary post-partum hemorrhage as bleeding which took place after the doctor had left the house. He distinguished the varieties of "concealed" and "evident." In the first variety the uterus distended, the cervix being blocked by spasm or clot. The causes of the condition were: Suddenly induced uterine inertia, which might be produced by emotional disturbance; partially detached pieces of placenta or membrane—these acted by keeping open the sinuses at the point of attachment, and were less dangerous when quite loose. Later in the puerperal period too early exertion, as in getting out of bed, might be a cause. The treatment, if the hemorrhage was concealed, was to pass the hand into the vagina, clear out the clots there, and then to pass the hand into the uterus, kneading the uterus at the same time with the other hand on the abdomen. In the mean time a hot douche should be made ready and administered at a temperature of 115° to 118° F.; a hypodermic injection of ergotine should be given. If the

hemorrhage was external, hot douches and kneading should be used, and, if these did not quickly succeed, the hand should be passed into the uterus. He found that he could pass the hand up to three days after parturition. In extreme cases he would compress the abdominal aorta. After the third day it may be necessary to dilate the cervix, and this he would do with Hegar's or bladed dilators. It was not generally necessary to give an anæsthetic; he would be prepared to plug the uterus with iodoform gauze if the hemorrhage was severe.

DR. WALLACE, of Liverpool, said that if it was from retained placenta he should class it as primary. He thought that hemorrhage was sometimes due to pressing the uterus down too firmly into the pelvis, and he never used the binder. He also thought that too hurried emptying of the uterus was a common cause.

DR. VAN SOMMEREN, of New South Wales, narrated a case in which all the usual means of treatment failed to stop the hemorrhage, and he succeeded in stopping it by compressing the abdominal aorta.

DR. RITCHIE agreed with Dr. Routh in his definition of secondary hemorrhage. He had found fibroids to be a cause. He had faith in prophylactic treatment, consisting in the use of tonics in the last months of pregnancy, especially strychnine; in not hurrying the birth of the placenta; and in not allowing the patient to become exhausted. He mentioned the importance of making an examination of the placenta. In reference to treatment, he would pass the hand into the uterus and inject hot water, and had found good to result from introducing a crystal of ammonia, iron, or alum into the uterus.

DR. BYERS, of Belfast, dwelt on the importance of careful management of the uterus in the third stage, and advocated turning the patient on her back immediately after the birth of the child. It was the greatest mistake to make the uterus push out the placenta before it was really separated. He always examined the uterine surface of the placenta and then examined the chorion. He had found distended bladder to be sometimes a cause of post-partum hemorrhage. Even without dilatation he sometimes found the curette sufficient.

DR. DONALD, of Manchester, had never seen secondary hemorrhage, except what had been caused by retained placenta, in hospital patients. In private patients he had sometimes seen it, due to too much food and constipation, and in those cases he gave calomel.

DR. J. D. WILLIAMS, of Cardiff, had used saline injections in severe cases. He thought secondary hemorrhage extremely rare.

DR. J. M. KERR, of Glasgow, thought that backward displacement of the uterus was sometimes a cause. If Credé's method was resorted to too soon, there was danger of pieces of placenta remaining.

DR. ROUTH, in closing, said that he had not mentioned fibroids, though he had known hemorrhage from that cause to come on a week after labor. He thought that the concealed variety was sometimes due to the use of ergot during labor, causing contraction of Bandl's ring. He hoped that the use of perchloride of iron had been abandoned; if used, he would apply it on a probe and not inject it. He did not believe in using the curette until the finger had been first introduced.

Puerperal Septicæmia.—DR. BYERS, of Belfast, read a paper entitled "A Plea for the Early Recognition and Treatment of Puerperal Fever." He said that puerperal fever was now more common in private than in hospital practice. The earliest symptoms were rise in the temperature and pulse rate. He had found the pulse to be 75 to 80 after delivery, quicker after forceps had been used, and the pulse rate might rise from other causes. He had seen cases of influenza

in the puerperal period, which caused difficulty in diagnosis. Constipation might also cause a rise. He urged the importance of a diurnal record being kept. If the temperature rose and no cause could be found, sepsis should be suspected; much time was often lost in giving quinine, antipyrin, etc. He would at once begin local treatment. The pelvic floor, vagina, and uterus should be examined, and tears of the perineum sutured and then dusted with iodoform. Cases especially liable to infection were the anæmic and those in whom the first stage of labor had been prolonged after rupture of the membranes. He advised irrigation of the uterine cavity by a gravitation douche of 1 to 4,000 perchloride solution. Antiseptic solutions, if used too strong, might cause death of the tissues and increase the danger. He used a large quantity of the solution, eight to ten pints. If the temperature and pulse fell, it need not be repeated; but if not, it should be used again, or, better still, continuous irrigation, as had been practised in France, with carbolic or boracic acid solution or lysol. This method had not received sufficient attention in Great Britain. The curettage caused no harm when carefully done. He did not, as a rule, do it before the fourth day of the patient's illness. Injections of antistreptococcic serum had not up to the present time shown very good results, but it might have a great future. Saline injections had been used. He kept up strength by stimulants and digitalis. Of abdominal hysterectomy for sepsis, he had had no experience.

THE PRESIDENT concurred, and said that if any rise of temperature occurred he would wash out at once.

Fleshy Mole.—DR. BERRY HART, of Edinburgh, read a paper on "The Symptoms and Nature of the So-called Fleshy Mole." The most marked change in the ovum in these cases was hemorrhage beneath the chorion. He narrated two cases: In the first, eleven months elapsed from the cessation of menstruation to the expulsion of the mass; and in the second eight and one-half months. Microscopic examination showed that the amnion was healthy and the villi of the chorion were perceptible, but the mucoid matrix of the connective tissue of the villi was increased. The mass was expelled in two forms: 1st, a piece of fleshy tissue; 2d, a sac containing a little liquor amnii and a shrivelled fœtus. In the first variety the portion which comes away is that which would ultimately form the placenta. The sequence of events is: Death of fœtus, which is sometimes retained, at others expelled; blood extravasation into the serotina, forming subchorionic exudations. This happens about the second month. In some the mass is expelled as early as four months and a half; in others retained to the eleventh month. When the condition was diagnosed, the cervix should be dilated and the uterus emptied.

THE PRESIDENT said such cases used to be known as "missed abortion."

Antitoxin Treatment of Puerperal Septicæmia.—DR. J. D. WILLIAMS read a paper on "The Value of Antistreptococcic Serum in the Treatment of Puerperal Septicæmia." Fourteen cases had been recorded by various authors: the earliest day for commencing the injections had been the fifth, and the latest the fourteenth. The dose had generally been ten cubic centimetres given by subcutaneous injection into the abdominal wall, the skin and syringe being first sterilized. Some good results had been obtained, but it was difficult to judge of them, as the serums used had not all been of the same strength.

Perforation of the After-coming Head.—DR. PURNLOW, of Birmingham, read a paper on this subject, in which he urged the choice of the roof of the mouth as a site for the operation, in preference to the one usually advised, viz., behind the ear.

Third Day—Friday, July 31st.

The Relative Advantages of Forceps and Version as a Means of Extraction in Cases of Moderate Pelvic Contraction.—DR. MILNE MURRAY, of Edinburgh, opened this discussion. He said that in cases of general pelvic contraction version was acknowledged to be inferior to forceps, but it was said that in cases of flat pelvis forceps were unsatisfactory and version was advised, the reason given being that forceps compressed the head in the antero-posterior diameter and so caused elongation of the biparietal diameter. He had made experiments to test the truth of this, and had found that it was possible to squeeze the child's head so as to reduce its longitudinal diameter one and one-half inches without increasing the transverse diameter. What happened was that a telescopic action took place, the frontal and occipital segments of the head slipping under the parietal, and the head also expanded in a vertical direction. This could be noticed when forceps were applied to the living, as the sagittal suture could be felt to descend, giving the operator a delusive idea that the head is descending. The explanation of the difficulties which had been experienced in the use of the forceps in the case of flat pelvis was that with the ordinary long curved forceps the direction of traction was wrong, tending to pull the head against the pubis. And he estimated that with a pull of fifty pounds as much as thirty-eight pounds of force might be wasted in this way. In the flat pelvis this was more likely to be the case than in the normal pelvis, because the inclination of the pelvic axis was greater and the pubis more horizontal. The use of axis-traction forceps avoided this, and he found that heads could be delivered by these which could not be extracted with ordinary forceps; and, as pointed out above, no amount of compression with ordinary forceps can increase the biparietal diameter of the head. He had delivered living children through pelves with conjugate of three inches, and in one case of two and three-quarters inches, by axis-traction forceps. He showed and demonstrated a pair of axis-traction forceps, in which he had made a modification which allowed the line of traction to be altered by moving the traction handle along a rod which projected at right angles from the traction rod. He had called these "adjustable axis-traction forceps." To sum up: Any case in which turning had been advised might be more efficiently dealt with by axis-traction forceps.

DR. PURSLOW, of Birmingham, thought Dr. Milne Murray had gone too far in absolutely condemning version in cases of contracted pelvis.

DR. FOTHERGILL, of Manchester, said that it had been urged in favor of version that the bitemporal diameter was substituted for the biparietal in passing through the conjugate. He thought that the same thing occurred with forceps.

DR. J. M. KERR, of Glasgow, said that in some cases, in which one side of the pelvis was more roomy than the other, some labors might be easy and others difficult in the same woman, according to the side to which the occiput was directed; and in such cases version was sometimes better when the occiput was found to be directed to the smaller side; when directed to the large side, forceps should be used.

DR. MURDOCH CAMERON, of Glasgow, thought much depended on the shape of the head, and he divided heads into "long" and "square." He showed an "antero-posterior" forceps of his own invention. He found that when forceps slipped it was generally due to the head being occipito-posterior.

DR. CONNEL, of Peebles, would never contemplate turning in preference to axis-traction forceps, and had found the latter also a powerful preventive of ruptured perineum.

DR. MILNE MURRAY, in closing, said that the blades should be applied fore and aft as regards the head, and not obliquely, as the latter caused a loss of the telescopic effect. He always used the axis-traction rods throughout, and never pulled on the application handles. He believed an occipito-posterior position would come round if left alone.

Hæmatometra and Pyometra.—MR. CHRISTOPHER MARTIN, of Birmingham, read a paper with this title. He said these cases were due to occlusion of the cervix, sometimes congenital and sometimes acquired. In the former the patient had suffered for some time from gradually increasing stenosis of the cervix, and in only one of his cases did the occlusion come on suddenly; in one of the cases in which the occlusion was acquired it followed amputation of the cervix for cancer. The treatment consisted in free incision of the occluded cervix and washing out the uterine cavity, stitching the mucous membrane of the uterus to that of the vagina, and allowing the patient to wear a rubber tube afterward. When the tubes were distended he advocated the removal of both uterus and tubes by abdominal section.

Walcher's Position.—DR. FOTHERGILL, of Manchester, read a paper on "Walcher's Position," which is to have the patient lying on her back on a table, with her sacrum on the edge, and her legs dependent, the feet being clear of the ground. The effect of this is to cause a rotation of the ilia on the sacrum and to increase the antero-posterior diameter of the pelvic inlet, while diminishing that of the outlet. Another effect which Dr. Fothergill had observed was relaxation of the perineum. He had made careful measurements with the woman in this position, and had found that the conjugate could be increased by as much as one-third of an inch. This manœuvre should always be tried before proceeding to symphyseotomy or craniotomy.

Hysterectomy for Fibroid Tumors.—DR. LE BEC, of Paris, read a paper on "Total Hysterectomy for Big Fibroids." His method consisted in opening the abdomen, tying the broad ligaments in sections, stripping off the bladder, and opening Douglas' pouch; and then, after removing the tumor, turning the stumps of broad ligament into the vagina, and stitching the peritoneum together over them. The paper, which the author himself read in English, was illustrated by numerous diagrams.

This concluded the business of the meeting.

Hemorrhage in Brain Surgery.—The control of hemorrhage is one of the most difficult problems in connection with the removal of cerebral tumors. Hemorrhage from the diploe is easily controlled by Horsley's antiseptic wax. For hemorrhage from the vessels of the meninges the ligature is an efficient means of control. If the dura be cut and an artery bleeds, the cut end can be tied just as any other vessel. If it be necessary to ligate a vessel in its continuity, the dura being unopened though with torn vessels, it can be secured by passing fine silk thread by means of the finest semicircular Hagedorn needle under the dura and around the vessel, care being taken not to wound the underlying cerebral veins themselves. For venous hemorrhage, the best method, also, is the ligature. Rarely can the vessel be seized by the forceps and a ligature applied. Pass by means of the semicircular needle of suitable size, a silk or cat-gut ligature through the cerebral tissue immediately below and around the vein, and then tie the vessel by drawing with equal force of the two ends, not constricting the vessel with so much force in tying the knot as to tear through its weak walls.—KEEN, *International Medical Magazine*, March, 1896.

Clinical Department.

IMPREGNATION—WHEN IS IT POSSIBLE?

By HENRY A. SHELLEY, M.D.,

NEW YORK.

VARIOUS views have been held by competent observers as to the time when woman may be impregnated during the lunar month. Some authors say only at the completion of the glandular function; others affirm that conception may occur at various times during the lunar month.

The illustrious Dalton thus writes in his classic work, "Human Physiology:" "The mature egg, discharged from the ovary, soon dies and is decomposed like any other portion of the body separated from its connections."

For some years I have studied the subject clinically. The orthodox members of two different religions furnished the subject matter. Orthodox Hebrew women observe the Mosaic law, living apart from their husbands for seven days after the monthly flow has ceased, making a total of at least twelve out of twenty-eight days in which sexual congress is prohibited. The fecundity of Hebrew women is proverbial. We read in Genesis: "And the Lord said unto Abram: And I will make thy seed as the dust of the earth; so that if a man can number the dust of the earth, then shall thy seed also be numbered."

Bearing in mind the dictum expressed by Professor Dalton as to the vital duration of the mature egg, it is reasonable to say that "ova are usually discharged from the ovary before the appearance of the monthly flow."

It is a common custom of strict Catholic women of the educated, upper classes of society to observe a rule of abstinence somewhat similar to that of Hebrew women. But the reason is altogether different. Such Catholic women do not wish children, for various reasons, their husbands assenting. By the way, Mr. J. S. Mill well remarks: "The fact itself of causing the existence of a human being is one of the most responsible actions in the range of human life." The law of Malthus is: There is a tendency in all animated existence to increase faster than the means of subsistence. This law is axiomatic, and is well worthy of consideration in social science. As the Catholic Church is most stringent as regards the violation or interference with the law of nature as regards sexual congress and its consequences, there remain but two things to do in order to avoid transgression of canon law—total abstinence from copulation or limitation of the act sexual to certain periods of the month, "the so-called sterile period," "*a quarto die post incepta menstrua*." What is the result clinically? A doctor, a Catholic, who faithfully observed this rule within his own household, when he found his own spouse *grosse*, sadly said to me: "Doctor, that sterile period ain't worth a d——." Frequently women who limit sexual intercourse to one or two days mid-period I find "to be with child." Alas! there is nothing certain in this transitory world but taxes and death.

To conclude, we may say in such cases as the above that the "sexual congress determines the ovipont."

These facts prove that the biological history of menstruation, bearing on impregnation, by Arthur Johnstone, is incorrect:

"It is only at the completion of the glandular function, that is, when the nidus is completely cleared out and cleaned and its epithelial covering removed, that the implantation of an ovum is possible. Therefore it is that the age and maturation of the impregnated ovum are to be reckoned from the end of menstruation."

My opinion is that whether the endometrium is in a morbidly hyperamic condition or not is a potent factor as regards conception. It is conceded that the true predisposing cause of abortion is irritability of the uterus.

Résumé: Facts sustain the following conclusions: "Ova are usually discharged from the ovary before the appearance of the monthly flow." Sexual congress often determines an ovipont (Coste). As a result coitus is often then followed by conception.

319 EAST ONE HUNDRED AND TWENTIETH STREET.

POISONING BY CANNABIS INDICA.

By G. G. FISCHLOWITZ, M.D.,

NEW YORK.

Owing to the rarity of cases of this nature, the following history is sent for publication:

On March 29th, at 11 P.M., I was hurriedly summoned to see Dr. L. C——, aged twenty-nine years, who was suffering from the effects of an overdose of the fluid extract of *cannabis indica*. The patient had, at 10:15 P.M., taken for his troublesome cystitis a teaspoonful of the above drug, after which he went to his office to read.

But feeling drowsy, he went to bed and awoke at 10:45 P.M., because of very troublesome dreams. He thought he had slept for hours, and had a feeling of tingling all over his body, especially around the angles of his jaws and in the region of his stomach, and of intense mental discomfort.

Realizing that an overdose had been taken, he allowed cold water to run over his head, which increased the discomfort about his jaws and abdomen.

He then started to read his "Materia Medica," in order to get an antidote; but though he found the proper page, he could not read, being unable to concentrate his mind. Becoming alarmed at his condition, he aroused his household and I was sent for. Before my arrival he had taken some mustard, which caused him to vomit freely.

On my arrival at 11:30 P.M. I found the patient excitedly, though in a happy frame of mind, walking up and down the sitting-room. After seating himself, he spoke very garrulously upon a number of subjects, but his memory of things past was very clear. He traced his ancestry back to his great-grandmother, who was melancholic, and he feared he himself would become insane.

He complained bitterly of the tingling and uneasiness in his limbs, and that his legs were as heavy as lead, and that when walking he felt as if wading through feathers. His tongue felt thick and leathery, and, fearing that he would become dumb, while walking he would shout out aloud, in order to correct that impression. His throat felt parched, the conjunctivæ were reddened, the pulse ranged from 100 to 118, and respiration was very rapid. He had no idea of time, minutes seeming hours, and voices in a neighboring room sounded to him as if coming to him from the top of the house. With distances he had no difficulty.

Upon attempting to drink a cup of coffee which was placed before him, he would forget to take the cup and would go on talking. Upon being reminded of the coffee, he brought the cup to his lips, but would fail to drink and continued talking.

About 1:15 A.M. I requested him to go to bed; but though much calmer than before, he hesitated about going to sleep, fearing that he would not awake.

At 2:15 A.M. he fell asleep and awoke at 5 A.M., with a severe frontal headache, but otherwise well.

In looking up the literature on this subject, I find but four cases reported in this country since 1883,

none of which ended fatally. Hamaker¹ reports a case of a physician who took forty-one drops of the fluid extract experimentally. Prentis² reports a case of poisoning by five drops of the fluid extract. Rusin³ reports two cases of poisoning by three-fourths of a grain of the solid extract.

1708 LEXINGTON AVENUE.

FOREIGN BODIES IN THE INTERIOR OF THE EYE.⁴

By W. A. FISHER, M.D.,

CHICAGO, ILL.

It is quite common practice to remove pieces of iron or steel from the interior of the eye with the magnet, many such cases having been reported. I wish to report two cases in which pieces of iron were found and extracted from the interior of the eye, yet one is strikingly different from the other.

With the literature at my command I can find nothing that equals in size the large piece of iron which remained in the eye so long without causing more serious results.

CASE I.—J. G. Graham, aged thirty-seven. Fourteen years ago, while he was driving spikes on a railroad, a piece of iron struck him in the eye, causing instant blindness. He was unable to work for about three months. Since that time he has been troubled about once a year, the attacks, at first lasting about a week, becoming more severe and lasting longer with each succeeding year.

February 13, 1896, he applied at my clinic at the Illinois Charitable Eye and Ear Infirmary, complaining of much pain, lachrymation, and photophobia. On examination I found the right eye atrophic and tender. Vision of the left eye was $\frac{2}{30}$. There were lachrymation and photophobia. The right eye was hopelessly blind and there was consequently no choice left as to treatment, enucleation being the only thing to do. He was at once anesthetized and the right eye removed. In cutting open the eye, the piece of iron was found to be completely encapsulated, while the lens was calcareous. The size of the piece of iron was eleven millimetres long, four millimetres wide (seven-sixteenths of an inch long, and more than one-eighth of an inch wide), and weighed two and one-eighth grains. The man was a scissors sharpener by occupation, and he went to work next morning, sharpened all the knives in the hospital, and expressed himself as feeling better than he had felt for three months.

This case seems remarkable when we take into consideration the size of the foreign body and the time it remained in the eye.

By way of comparison I will now report an injury from a much smaller piece of iron I removed with the magnet, and which caused destruction of the eye, necessitating its removal two weeks after the accident.

CASE II.—J. P. Roth, aged four years and ten months, patient of Dr. Harsha. November 9, 1895, the right eye was injured while he was playing with two hammers. November 11, two days after the accident, I saw him in my office with Dr. Harsha. There was a scar in the ornea, also a corresponding scar in the iris. The vitreous was completely clouded; there was no reflex. A diagnosis was made of foreign body in the interior of the eye. The child was asleep and when awakened was very irritable. I was unable to locate the foreign body on account of the restlessness

and the age of the child. As the foreign body, if left in the eye, would in all probability destroy it and subject the good eye to great danger, I decided to remove it and endeavor at least to save the globe, as it is often impossible to get children of this age to wear an artificial eye. In removing the eye I realized the importance of thorough antisepsis in such cases, being very particular to sterilize the instruments, cleanse the eye, and, in fact take every precaution as to cleanliness. When everything was ready the patient was given chloroform, the conjunctiva was opened, and an incision made in the sclera with a Graefe knife. The curved tip of a magnet that was attached to a three-cell storage battery was then introduced, and with but little effort the foreign body was located and drawn to the surface. In trying to extract it through the scleral opening, which seemed too small, it slipped from the magnet and fell into the vitreous. The opening was therefore enlarged and the piece of iron removed. As in similar operations about the usual amount of vitreous was lost. The eye was thoroughly cleansed with 1 to 5,000 bichloride solution, and the conjunctiva stitched, cleansed again, and one-per-cent. atropine solution instilled and the eye bandaged. The child slept well that night, the bandage was removed the next morning, and the eye was again cleansed with 1 to 5,000 bichloride solution, the application of atropine repeated, and the eye bandaged. There was no reaction following the operation. Atropine was instilled every day thereafter, and antiseptics were used as often as practicable. Everything progressed nicely until the fourteenth day, when a swelling appeared at the site of the scleral opening. The globe was now filled with pus. Evisceration being the only thing to do, Dr. Harsha again administered chloroform and the operation was performed. At the end of two weeks the child was fitted with an artificial eye and has worn it continually since. I report these two cases to show what the eye may or may not tolerate.

It is not always possible to remove pieces of iron or steel from the interior of the eyeball with the magnet. It has been my misfortune to make a thorough search for a piece of metal in the vitreous with a good magnet attached to a good storage battery and not find it until I had removed the eye. In my hospital work I have witnessed many similar failures. I think any one who has had much clinical experience has at times met with the same results. There are so few misfortunes of this kind, however, attending the use of the magnet in extracting pieces of iron or steel from the eye that we are not justified in abandoning the use of the magnet, but on the other hand it should always be employed, unless, perhaps, the metal has become encapsulated and the eye is quiet. Even in these cases the patient would often be better for an operation.

About two years ago in this society I saw two subjects who had pieces of metal encapsulated in the fundus of the eye. They were quiet at that time and one of them had good vision. I have had the one that had good vision as a private patient since that time. This was a patient of Dr. Tilley's. July 5, 1895, Dr. Tilley being out of the city, I was called to see this patient (Mr. T. W. F.). He had injured his right eye the day before with a firecracker. I recognized the patient as the one whom Dr. Tilley had shown in the society with the metal in the fundus and who had at that time vision of $\frac{6}{12}$. The metal had not injured the lens in its entrance, but at the time I saw him the lens was opaque and the eye far from being in a state of rest. The right eye soon cleared up and I have lost sight of him, but I am sure he would be much better with the eye enucleated than to have it in the condition it was in when I saw it.

If one is sure of having a piece of metal in the eye, and the media are not clear but are without serious in-

¹ Hamaker: Therapeutic Gazette, Detroit, 1891.

² Prentis: Therapeutic Gazette, Detroit, 1892.

³ Rusin: Southern Medical Recorder, Atlanta, 1890.

⁴ Read before the Chicago Society of Ophthalmology and Otology, April 14, 1896.

flammation, it is well to wait for the media to become clear. If there is serious inflammation and the media are not clear, nothing will be gained by waiting.

The results of magnet operations are very various so far as vision is concerned. Many patients who are reported as having good vision are reported too soon, but enough successful cases are reported to justify us in using the magnet in all recent cases. When the metal is in the anterior chamber the results are nearly always satisfactory. In removing from the anterior chamber metal that has become embedded in the iris it is best to use a flat blunt electrode. The electrode should be introduced in the anterior chamber and the metal dislodged before connecting the current. The foreign body having been dislodged, the button on the handle of the electrode may be touched and the metal removed, thus preventing prolapse of the iris.

Churning the vitreous is to be avoided. Cocaine is as good as profound anæsthesia in adults. Thick blunt electrodes are to be preferred to thin pointed ones.

Air bubbles are always a sure sign of foreign bodies in the eye.

Sometimes a piece of metal can be located by passing the electrode over the sclera. The patient will complain of pain only as the instrument passes over the metal.

It is useless to probe for foreign bodies in the vitreous.

It is not wise to try to remove a foreign body from the interior of the eye through the opening made by its introduction. It is better to make a larger opening and avoid introducing the instrument so many times.

In conclusion I will say that the possibility of preserving the globe and often useful vision warrants us at all times in using the magnet in all cases in which metal is in the interior of the eye.

103 STATE STREET.

TREATMENT OF PNEUMONIA.

By S. H. VANDOREN, M.D.,

SAYBROOK, ILL.

REALIZING that no safe and certain cure for pneumonia is given by any medical work extant in the English language, I desire to state briefly a few facts, which, I hope, will be instrumental in the hands of a part of the ninety thousand of earth's humanitarians toward lessening the fearful ravages of this chief lieutenant of death in all countries.

I shall not enter into the symptoms or the pathology of pneumonia, as these can be learned from many medical works of the day. Upon those points there is no dispute.

The world to-day is without a successful treatment and that is what I will supply. Medical men are as suddenly struck down by it as are their patrons.

The treatment upon which in my experience most reliance can be placed is as follows: Counter-irritation to chest, followed by hot poultices constantly applied until all danger is past.

Nothing new, say a thousand voices at once. No, but wait. I do not believe any person ever had pneumonia when the liver and kidneys were in a normal condition. We must establish a free secretion of all the important organs of the system.

First we would give:

℞ Tr. aconiti,
Tr. bryoniae.....āā gtt. x.
Tr. digitalis..... 3 i.
Potassii nit. 3 ss.
Fl. ext. ipecac..... gtt. x.
Syr. pruni virg ... q.s. ad 3 iv.
M. S. For adults, teaspoonful diluted every hour until

patient is better; then only as seems to be required, say every three hours while fever lasts.

I use the best imported German tinctures. They must be reliable.

We have now started right. In an active practice for twenty years I never saw a case that did not need free catharsis. I think any compound employed should act through the blood and intestinal tube, and be capable of emptying the alimentary canal by its effect upon the mucous membrane lining the intestinal tube, for if these toxic ptomains remain in the system they may destroy it, and this is why opiates of all kinds kill the patient—they check the elimination of those deadly poisons from the system, and cause debility and irritation in the lungs to increase.

So we would give:

℞ Ext. rhei,
Ext. jalapæ et sennæ āā 3 ij.
Sodii bicarb.,
Potassii tart.....āā 3 iss.
Tr. capsici..... 3 ss.
Ess. menth..... 3 ij.
Syr. simp q.s. ad O i.

M. S. Tablespoonful diluted every three hours until the bowels operate three or four times thoroughly; then daily as required to keep up free action.

In forty-eight hours after this treatment has been instituted give:

℞ Syr. ferri iodidi..... gtt. xx.
Strychninæ sulph..... gr. 3̄.
Atropinæ sulph..... gr. 3̄.
M. S. Give every four hours for one dose as above.

By this treatment you sweep out of the system the poisons that if permitted to remain produce death.

The last prescription strengthens the heart and lessens in a very marked degree the pulmonary pressure in the lungs, and the irritation rapidly subsides.

I was taught to depend upon about ten drops of syrup of iodide of iron, three times daily, in such cases for its alterative and tonic effect in assisting to clear up a hepatic lung; but such small doses are not sufficient in most cases to accomplish that result. I frequently give in acute bronchitis, especially in the aged, forty drops every four hours, until marked improvement is noted. Furthermore, the careful physician will know when to lessen the dose of strychnine.

As a rule, after I have the patient on the last prescription twenty-four hours, I reduce the strychnine to about one-one-hundred-and-fiftieth grain three or four times daily, and maintain a tolerably free circulation all through the case.

In conclusion, I want to impress upon the minds of members of the medical profession that it is not necessary for any ordinary case of pneumonia less than seventy years old to die if treated upon these lines. If the above doses do not promptly control the disease, I increase the doses until I get the system profoundly under control and then maintain that effect.

As regards the use of alcoholic stimulants, best Holland gin should be given from the start or in twenty-four hours after the chill. Why do we give gin? For two reasons:

1st, to maintain a better circulation of the blood.

2d, and most important of all, to assist the kidneys to freely eliminate the various poisons that have the natural tendency in these cases to accumulate in a body.

Colles' Immunity.—By this is meant that which is shown by those healthy mothers who, owing to syphilis in the father, have borne syphilitic children, but have themselves apparently escaped infection. This immunity has been proved in thousands of cases, and there is no longer any doubt that it may exist.

Surgical Suggestions.

Vaginal versus Abdominal Section.—Vaginal section: (1) A shallow and wide pelvis in a thin woman. (2) Exploration of the pelvis. (3) Visceral adhesion in true pelvis. (4) Displaced and adherent uterus. (5) Smaller ovarian cysts, especially the intraligamentous and parovarian. (6) Smaller fibroids, especially the soft. (7) Extra-uterine pregnancy, up to seventh month and after death of fetus. (8) Pelvic hæmatocele. (9) Puerperal hysterectomy. (10) Acute inflammation of the appendages, with peritonitis, involving cul-de-sac. (11) Inflammatory destructive diseases of the appendages, including tuberculous disease. (12) Pelvic abscess pointing downward. (13) Conservative operations on appendages that lie in the true pelvis.

Abdominal section: (1) A narrow and deep pelvis, especially if deformed. (2) Explorations above the true pelvis. (3) Visceral adhesions in false pelvis or above. (4) Large ovarian cysts, especially multilocular, with colloid contents. (5) Large fibroids, especially the firm and hard. (6) Extra-uterine pregnancy at time of rupture and of term. (7) Extra-uterine pregnancy, with tumor wholly above the brim of the pelvis and not in relation with the uterus. (8) Pelvic abscess pointing upward. (9) Conservative operations under conditions unfavorable to vaginal section, such as narrow and deep, or a deformed pelvis that is contracted. —WILLIAM M. POLK, *Canadian Practitioner*, February 8, 1896.

Malignant Disease of Uterus.—1. Cancer of the cervix uteri, if left without surgical interference, always kills. 2. The disease in most instances is primarily a local process. 3. Early hysterectomy will cure quite a percentage of these cases. 4. The microscope, while a great diagnostic aid, is not infallible in its findings. 5. The experienced surgeon is warranted in resorting to hysterectomy, even in doubtful cases. 6. Every malignant gravid uterus should be removed before the disease has advanced beyond the period of a probable cure.—CORDIER, *Tri-State Medical Society*, Chicago, April, 1896.

Club Foot.—In infants who have not walked on a congenital equino-varus the deformity can be easily cured by manipulation by correcting first the varus and later the equinus, and holding the foot in plaster-of-Paris dressing after each manipulation until overcorrection is obtained. The child should then wear a retention apparatus for a year after it has learned to walk.—TAYLOR, *Maryland Medical Journal*, April 11, 1896.

Nocturnal Emissions.—The cause of impotency, of abnormal seminal emissions, and of premature ejaculations is in most cases an intense hyperæsthesia of the deep urethra. Nocturnal emissions occurring with greater frequency than once in ten days are indicative of some pathological condition which requires treatment; seminal discharges taking place in the daytime, when the patient is awake, are of serious import, however infrequent they may be; true spermatorrhœa is very rare.—LAMPHEAR, *American Journal of Surgery and Gynecology*, February 18, 1896.

Drainage of Abdominal Cavity.—Drainage of the abdominal cavity is an expression of the present imperfect state of surgery. It is often an unavoidable evil. It should be limited to appropriate cases, and it is therefore well that the indications for it should be laid down clearly, so that we may have eventually some definite rules that will guide the surgeon in his abdominal work. There are now no fixed rules. Some

surgeons avoid drainage whenever possible; others drain as a rule. If I were permitted to pass my judgment on this question as a whole, I would say that the surgeon who has the ambition to operate quickly, to make an impression on the bystanders, should drain frequently; while, on the other hand, the surgeon who proceeds with his work carefully, step by step, with plans well laid out, with his practical knowledge resting on a firm pathological basis, will drain only in exceptional cases.—SENN, *American Gynecological and Obstetrical Journal*.

Floating Kidney.—(1) Operate on all movable kidneys which are diseased, varying the operation according to the condition present. (2) When mechanical troubles or pain are present, try a supporting bandage. If the symptoms disappear, then give to the patient the opportunity of choosing between operation and mechanical support. If a bandage does not give a good result, operate. (3) When hysterical or neurasthenic symptoms are present, then try the bandage, and do not operate unless it fails to give satisfactory results. (4) In cases of general abdominal relaxation employ the abdominal supporter, and do not operate unless the movable kidney itself is the cause of distressing symptoms. After the operation it is still necessary to use the bandage. (5) When a movable kidney does not give rise to serious symptoms, advise the use of a bandage.—ALBARRAN, *An. des Mal. des Org. Génito-Urinaires*, vol. iii., p. 577.

Bacterial Products.—Drs. Vaughan and Novy have determined the chemical products of bacteria to be: 1. Ptomaines, which are either toxic or non-toxic. 2. Toxalbumins. 3. Ferments. 4. Acids. The ptomaines are transitional products and resemble the vegetable alkaloids. Vaughan says: "The germ produces toxins by splitting up pre-existing compounds." An example of toxins is the typho-toxins, and of the non-toxic ptomaine methylamin. The toxalbumins are albuminous substances. In this class of products are the active principles of the various toxin serums, as tuberculin and tetanin. The principal ferment is the peptonizing ferment already mentioned. All these have a part in pyogenesis. When the toxins are absorbed and carried to the nerve centres we get the fever and other constitutional disturbances of suppuration.—DUNCAN, *Kansas Medical Journal*, April 18, 1896.

Dressings.—Any surgical wound dressing should be absorbent, to admit of the ready impregnation with medicinal substances and to absorb discharges. The substances in most common use are lint, absorbent cotton and gauze, tow, oakum, jute, wood wool, moss, peat, and pine sawdust.—*American Text-Book of Surgery*, p. 1,159.

Profeta's Immunity.—"La loi de Profeta," according to Fournier, is the immunity of the children of syphilitic parents, either or both of whom are syphilitic.—*American Text-Book of Surgery*, p. 134.

Hip-Joint Disease.—There has been a diversity of opinion as to the tissue in which the disease exists primarily, some surgeons asserting that its frequency of commencement is first in the synovial membrane; others in the capsule; others in the ligamentum teres; and still others, constituting the largest majority, contend that its primary manifestation is in the development of a tuberculous osteitis in the head of the femur or the cancellated bone tissue at the bottom of the acetabular cavity, the same principle holding true here as elsewhere in the predominance of the epiphyseal affection. The examination of a large number of specimens after resection of the hip-joint favors the supposition that an osteitis, resulting from an implan-

tation and development of the bacillus tuberculosis in the cancellous tissues of the bony elements of the joint, is the starting-point of this disease most frequently by far, in children at least. In adults the synovia membrane of the joint is often the first tissue to be affected.—CHARLES T. PARKES, *Clinical Lectures*, pages 457 and 202.

Tuberculous Meningitis.—Dr. Lamphear has advocated an operation in tuberculous meningitis which, so far as I know, has never been tried—namely, opening the skull and washing out the meningeal spaces, as we do the belly in tuberculous peritonitis. He reasons that the peculiar disappearance of the tuberculous process in peritonitis treated by flushing the abdomen, leads to the conclusion that a similar result might be anticipated in tuberculous meningitis when complicated with hydrocephalus.—*American Journal of Surgery and Gynecology*, vol. ii., p. 143, January, 1896.

Rupture of the Quadriceps Extensor.—Dr. Walker (*American Journal of the Medical Sciences*, p. 647), in a paper on the aforesaid subject, draws the following conclusions: 1. In recent cases in which there is not much effusion and the joint is apparently not opened, and in which the separated ends can be approximated and detained by suitably adjusted pads, the mechanical treatment may be carefully considered. In the hands of the intelligent general practitioner this method may be expected to bring about a complete recovery in the larger number of cases. From nine to twelve months will be required to re-establish fully the normal functions. 2. A too prolonged fixation in bed is unfavorable to an early recovery; therefore early massage and passive motion are strongly advised. 3. The skilled aseptic surgeon who primarily resorts to the operative method in suitable cases (but the age and vitality of each patient must be most carefully considered) may quite reasonably hope to obtain a better result in a larger number of cases and save his patient three to six months' time. Catgut, kangaroo tendon, or silkworm gut should be used, and when there is much effusion drainage should also be employed. 4. When the separation is greater than one and one-half inches, or when the case has not recovered under the mechanical treatment, the operation is indicated. 5. As the length of time required for treatment is a very important consideration, so the operative method, which has diminished this period and also succeeded in a larger number of cases without increasing the danger, will be more often indicated and more frequently applied in the hands of the skilled surgeon.

Treatment of Puerperal Sepsis.—1. Suspected infection of the birth canal should be confirmed when possible by a bacteriological examination of vaginal secretions, and every means of differentiating from other affections be resorted to, that they may be treated rationally either by medicine or by surgery. 2. Irrigation and antiseptics destroy the nutrition of the parts when continued and, furnishing increased moisture, improve the field for the development of micro-organisms, aside from the danger of death resulting from the antiseptic used. 3. The birth canal can be kept comparatively dry by absorbent dressing, removing the culture media and arresting the development of germs and infection until the abraded parts have healed.—MILLER, *American Journal of Obstetrics*, November, 1895.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

OMNIUM GATHERUM FROM CARLISLE.

LONDON, August 7, 1896.

THE lapse of a week since leaving Carlisle has not sufficed to turn professional gossip into its accustomed grooves. Wherever we meet, one of the earliest questions is, "How did you like Carlisle?" or "What did you think of the meeting of the B. M. A.?" or something equivalent. A very nice place to visit is the border city, with its wide, well-kept streets, substantial buildings, and hospitable, big-hearted Northern inhabitants. Carlisle, too, has a history of which it may well be proud and offers archæologists no slight attractions. It has, further, a medical history, which history and that of the worthies of the district were well told in the address of the president. Some diffident people feared the meeting might be a failure, as coming after London, but the event has justified the courage of the Cumbrians, who may continue to boast in the words of their old song:

"Canny au'd Cumberlan' caps 'em a' still."

The district around the border city is one of great interest and well worth full exploration. A number of excursions were arranged by the local committees, including one to the "Land of Scott" and another to the lake district. Cricket, lawn tennis, golf, etc., were accessible. A conversazione and a dance, garden parties, and other entertainments galore were provided by the Cumbrians, and the 1896 meeting may fairly be cited in support of the frequent taunt that these congresses are attended more for the sake of dissipation than science. I should mention that parties were conducted through the cathedral, the castle, and Tullie House by Chancellor Ferguson, and the splendid collection of birds in the museum was a great attraction, as to which the Rev. H. A. Macpherson acted as the kind cicerone.

Dr. Barnes is an excellent president, and the choice of the subject of his address was most appropriate. It must be confessed, however, that his voice could not adequately fill the room, and many were therefore unable to follow all his utterances. I hear, however, that your special reporters secured good places and have sent you a full abstract. The local press was by no means gratified with the treatment meted out to its representatives, who were excluded from the most lively proceedings. Gentle hints, not to say remonstrances, were thrown out about "meetings with closed doors" and the curious "traditional reserve" of the doctors being perhaps connected with their "proverbial differences."

It was very amusing to see the energy of a door-keeper in clearing the room of reporters at some of the general meetings. He included in his orders the representatives of medical journals, assuring them the meeting was private and out they must go. The absurdity of thinking the doings could be kept secret when so many members were present should have been manifest to the managing clique. As a member I could not be excluded, and I write shorthand, as no doubt many other members can, besides which, with every dinner table discussing the secrets, they were all "open" ones indeed. It was natural, perhaps, for these managers to wish to avoid all discussion of their conduct in the libel action, Kingsbury v. Hart, but Dr. Kingsbury had taken effectual means to prevent this. He had printed a pamphlet containing his history of the case *ab initio* and a full report of the trial.

in which he triumphed and which the council confessed to have cost £1,300, and yet they were not manly enough to acknowledge any mistake. It was very laughable to see Mr. Hart making anvil and hammer of his fists to emphasize the assertion in staccato falsetto, "I—would—do—the—same—again—in—the—same—case." No, no, Mr. H., not if you had to pay the costs! Dr. Kingsbury's pamphlet was freely distributed and is very caustic. It asserts that agents were set to work in Blackford, Manchester, Liverpool, and Preston "to try by hook or by crook to hunt up witnesses against him, but they failed to find one honest man in all Lancashire whom they could induce to give evidence," while "twenty-one of the leading professors and consultants of the county volunteered their services and were in court to support him." But the defendant did not appear. He started on the yacht trip which he advertised in the *Times* the day before the trial, and Dr. Kingsbury speaks of him as "the gentleman who had only the courage to run away." It was suggested at the trial that he was ill, but no evidence was given; in the debate at Carlisle it was said that anxiety lest he should be asked the name of his informant prompted his non-appearance. These explanations do not agree, but what matters? The case is over. Dr. Kingsbury has vindicated his conduct and shown that the enormous influence of the association cannot crush an independent man who has nothing to be ashamed of. The lesson was needed, and it is to be hoped will be laid to heart in in both the editorial and advertisement offices of the *Journal*.

How the evidence of Sir D. Duckworth, Sir T. Stokes, and Dr. Cousins broke down at the trial was duly recorded in your columns at the time. The fuller light shed on the matter in Dr. Kingsbury's pamphlet confirms the opinion then expressed. As to advertising, the lesson will now perhaps be learned that what is sauce for the general practitioner is sauce for the consultant.

Dr. Kingsbury scored a success, for although he had to modify a resolution he submitted, he carried that part of it which invited the council to draw up a code of ethics to be submitted to the association. It might seem that some of the council were scarcely suitable persons to entrust with this task, but no doubt their recommendations will soar above their practice.

Ignorance of ethics was openly professed by some and a definition demanded. But on Wednesday a section of ethics was opened under the presidency of Dr. l'Anson, who told his audience in his address that "their ethics were comprised in their duty to their brother practitioners, their patients, and the world at large." This is comprehensive enough, though surely "the world at large" includes brethren and patients. But the president went on to particularize by adding to his statement "and the necessity of upholding by any and every means in their power the honor and dignity of their profession." I do not desire to criticize these rather loose expressions; the subsequent discussions would have been more edifying if some of the speakers had conformed to the president's description. For it cannot contribute to our honor and dignity to give way to temper in discussing burning questions, and I am sure it is contrary to so-called ethics for speakers to hurl opprobrious epithets at one another.

The annual dinner went off with the usual *éclat*. The bishop was present and returned thanks for the toast of the clergy and ministers of all denominations. He humorously pretended that he nearly fell "into a trap" by speaking in an assembly of doctors of the other denominations as "irregular practitioners," and then, referring to the next toast, the military one, claimed them as "auxiliary forces" and paid them full compliment as brothers in arms.

Surgeon-Captain Witchurch, who won the Victoria Cross for his heroism at Chitral, also spoke and was received as enthusiastically as when the gold medal was presented at the general meeting.

The temperance breakfast is now regularly looked for. For some twenty-five years the National Temperance League has invited the members to a breakfast. This league is devoted to the spread of temperance by moral suasion. Sir Wilfred Lawson, who is the leading advocate of legislative suasion, was also present, and some delightful humorous passages were exchanged between him and the bishop, making this one of the most successful entertainments of the kind.

The journey back to London on Saturday was much retarded by the crowded state of the line carrying thousands in the opposite direction. Members who stayed until Monday, the bank holiday, were doubtless much more inconvenienced. Not a few took the opportunity of a few days in the lake district.

The Third International Congress of Dermatology has been sitting in London all the week, but notes of its proceedings must stand over and for once the metropolis give place to the border.

OUR BERLIN LETTER.

(From our Special Correspondent.)

RENAL DIABETES — URIC-ACID DIATHESIS — HOT-AIR
FIXATION OF BLOOD SPECIMENS—DIPHThERITIC
MYELOCYTHÆMIA.

BERLIN, August 8, 1896.

A RECENT lecture upon renal diabetes by Dr. Klemperer aroused a more than usually interesting discussion. The views enunciated by Dr. Klemperer may be summarized briefly as follows:

In the healthy person, sugar is stored up in the liver as glycogen, but if excessive quantities of carbohydrates have been taken a certain amount passes the liver, enters the blood unchanged, and is excreted by the kidneys as sugar.
